Micro permanganate acid ashing method for determination of serum iodine EVELYN B MAN and DOROTHY A SIEGFRIED (by invitation) *Yale Univ School of Medicine, New Haven, Conn*. Protein bound iodine in duplicate 1 cc aliquots of blood serum is precipitated with solutions of zinc sulfate and sodium hydroxide in micro flasks which fit into 250 cc centrifuge cups. The centrifuged precipitate, after decantation of supernatant fluid, is washed about 3 times with iodine free water to remove as much inorganic iodine as occurs during Lugol's administration. The precipitate is heated with solutions of potassium permanganate and sulfuric acid. Without transfer from the precipitation flask, the digest is reduced with acid arsenite solution and iodine distilled through a micro condenser into a dilute acid arsenite solution. Iodine in the concentrated distillate is measured by recording, during about 5 minutes, the color change with ceric sulfate in Chaney's constant recording colorimeter. The average of duplicate recoveries of inorganic iodine added to zinc hydroxide blanks after centrifugation but before digestion was 2.2 for 2.0, 4.8 for 5.0, 9.2 for 10.0, and 15.1 for 15.0 gamma % of iodine. Serum hormonal iodine determined by this microprocedure has checked with values obtained by the Riggs, Man macro permanganate acid ashing method. This method requires only 2 cc of serum for duplicate determinations. Precipitation, digestion and distillation are continued in the same micro flask, without transfer. Different concentrations of acid arsenite solution are used for reduction of the digest, collection of iodine in distillate, and quantitation of iodide by ceric sulfate. Constant records of color change eliminate the problem of exact timing and facilitate recognition of irregularities in color fading produced by contaminating substances in the distillate.

Effect of methyl-bis(beta-chloroethyl)amine on blood constituents GEORGE H MANGUN *Dept of Laboratories, Henry Ford Hospital, Detroit, Mich*. Hartman and Mangun demonstrated that the nitrogen mustards are capable of inactivating viruses

and bacteria in the presence of blood plasma and whole blood, and that a variety of plasma and red blood cell constituents are essentially unaffected or only slightly affected by the sterilizing dosage of Methyl-bis(beta-chloroethyl)amine (HN2) (500 mg/l). An exception is the prothrombin time of citrated plasma. When undiluted citrated plasma is treated with 500 mg/l of HN2 at pH 7.0, the apparent prothrombin concentration (Quick's one-stage method) drops progressively over a 3 day period at 4°C to about 20-30% of its original value. The effect of HN2 has been studied on separated preparations of bovine thrombin, prothrombin, fibrinogen and accelerator globulin. When treated with 500 mg/l of HN2 at pH to 7.5 at 4°C the following changes were noted. Thrombin (0.5 mg/ml of Seeger's preparation #480904, 17,800 U/mg of tyrosine) is slowly inactivated, showing about 1/3 of its original activity at 3 hours and 2-3% at 20 hours. Prothrombin (Seeger's #481025, about 500 U/mg) is rapidly inactivated in 0.5 mg/ml saline solution, about 1% of the control activity being present at 2 1/2 hours and less than 0.5% at 20 hours. Accelerator globulin (not purified, treated in 1:10 saline) after 20 hours was about 5% of the control activity. The clotting rate and total fibrinogen (Seeger's #470712, 92% clottable) precipitated by thrombin were unaffected by the sterilizing dosage of HN2.

Enzymatic degradation of thymidine L A MANSON (by invitation) and J O LAMPEN *Dept of Biological Chemistry, Washington Univ School of Medicine, St Louis, Mo*. In a previous study we obtained both phosphorolysis and arsenolysis of hypoxanthine desoxyriboside by enzyme preparations from calf thymus and rat liver. A desoxypentose-5-phosphate was isolated as a product of phosphorolysis and evidence was obtained for its formation by way of the 1-phosphate ester (*Abstracts*, Sept 1948 meeting of the American Chemical Society). The mechanism of the action of nucleosidase on the desoxyriboside appears identical with that demonstrated for the riboside by Kalckar, Deutsch and Laser (*Ztschr f physiol Chem* 186 1, 1930) and Klein (*Ztschr f physiol Chem* 231 125, 1935), using phosphate and arsenate buffers, showed the existence of a separate pyrimidine nucleosidase. We have studied the degradation of thymidine by preparations from dog bone marrow and calf kidney and have again observed both an arsenolysis and a phosphorolysis. The products of the arsenolysis are free thymine and the free sugar. Free pyrimidines inhibit this reaction. The kinetics of the arsenolysis will be discussed. Thymidine was not degraded by a hemolysate of rabbit erythrocytes or a purine nucleoside phosphorylase preparation from rat liver. The products of the phosphorolysis of thymidine are free thymine and a phosphorylated form of the sugar. The evidence for

the latter is that an uptake of inorganic phosphate occurs and little free sugar is found. Also the addition of hypoxanthine increases the rate of formation of free thymine. The preparations contain purine nucleoside phosphorylase, hence this result is in agreement with the formation of a phosphate ester which is removed by reaction with the hypoxanthine. We have not observed any requirement of a dialyzable cofactor (other than phosphate or arsenate) by the pyrimidine nucleosidase.

Groups involved in the Zimmerman and Kober reactions. H. W. MARLOW (introduced by H. C. TIDWELL) *Dept of Biochemistry, Southwestern Medical College, Dallas, Tex.* The colored compounds formed by the Zimmerman and the Kober reagents are still unknown, hence it has not been possible to determine the exact groups involved in these tests. In the Zimmerman reaction, it has been postulated that a methylene group adjacent to a carbonyl is necessary for color development. In the Kober reaction the presence of an α -diketone was at one time believed to be responsible for the specific color development. With the synthesis of various 16 substituted steroids, it is now possible to shed further light on these color tests relative to the groups involved. Present data indicate that in the Zimmerman reaction a carbonyl group at C₁₇, with adjacent methylene group at C₁₆, is necessary for the highest color development. Steroids in which a carbonyl group is present at C₁₆ with two adjacent methylene groups, however, give no color with the Zimmerman reagent. This finding is not in agreement with the contention that all $-\text{CH}_2-\text{CO}-\text{CH}_2-$ groupings (as in acetone, in ethyl acetoacetate and in cyclopentanone) yield strongly positive Zimmerman reactions. 16,17-di-ketosteroids also give a negative Zimmerman. With the Kober reagent, 16-diketosteroids produce no color. However, 16-keto, 17-hydroxysteroids give an intense Kober reaction. Also 16,17-diketosteroids produce no color with the Kober reagent.

Incorporation of C¹⁴-formic acid into nucleic acid fractions of rat and pigeon. WALTON H. MARSH (introduced by HARLAND G. WOOD) *Dept of Biochemistry, School of Medicine, Western Reserve Univ., Cleveland, Ohio.* While other workers have shown that labeled formate is incorporated into uric acid and hypoxanthine in pigeons, it has not previously been demonstrated to enter the nucleic acid fractions of birds or mammals or to be oxidized by the bird. Radioactive formate was fed to a pigeon and injected intraperitoneally into rats, the time of sacrifice being 3 days in the former and 14 hours in the latter. The nucleic acids of both the rat and the pigeon were radioactive, although the activity was only a small per cent of that administered. The adenine and the guanine from the pigeon nucleic acids were radioactive. It was also found that the formate which was given to a pigeon

at the rate of 0.7 mm/hr, was oxidized to CO₂ on the average of 6.5% for the first 12 hours. The rate of oxidation increased very rapidly throughout this period. This oxidation probably was not entirely due to intestinal bacterial action since pigeon liver homogenates were shown to oxidize formic acid at the rate of 0.2 $\mu\text{m/hr/gm}$ wet weight of tissue. From the respiratory C¹⁴O₂, only 5% of the activity in the purines could have come from the incorporation of CO₂ whereas, in the rat, on the basis of the high formate oxidation (W. Sakami, *J. Biol. Chem.* 176:995, 1948), all the radioactivity of the purines could be accounted for by CO₂ fixation. The location of isotope in the purines may shed light on the mechanism of synthesis.

Determination of fumaric acid in animal tissues by partition chromatography. LAWRENCE M. MARSHALL (by invitation), JAMES M. ORTEN and ARTHUR H. SMITH *Dept of Physiological Chemistry, Wayne Univ. College of Medicine, Detroit, Mich.* A method for examining the fumarate content of tissues has been devised. It employs column partition with silica gel as the mechanical support for the aqueous phase over which passes an amyl alcohol-chloroform mixture, the non-aqueous, mobile phase. The sequence of organic acids liberated by the mobile phase from the silica gel column is directly related to the distribution coefficients of the solutes with reference to the system employed. Citric, malic, lactic, succinic, fumaric, beta-hydroxybutyric, acetic and benzoic acids represent a partial list of acids arranged in inverse order of their release from the column. Glutamic, aspartic, and nicotinic acids, like citric, are delivered after fumaric acid. The effluent acids are titrated with 0.004N sodium hydroxide. When the fumaric acid emitted from the column is collected in successive fractions having geometrically increasing volumes, the concentrations of fumaric acid plotted against the fraction number describes a curve which approximates the normal curve of error. The observed curve agrees closely with a theoretical curve calculated from the binomial law. Recovery studies demonstrated the applicability of the technique to animal tissues. The fumarate concentrations, expressed in mg %, in several tissues of the fasted adult rat maintained on a stock diet show the following values: brain, 15; kidney, 9.5; liver, 7.8; gastrocnemius muscle, 2.3; and blood, less than 0.3. Preliminary studies indicate the applicability of the foregoing procedure to the determination of other related organic acids in animal tissues.

Protein changes in the developing chick embryo. MARGARET E. MARSHALL (by invitation) and H. F. DEUTSCH *Dept of Physiological Chemistry, Univ of Wisconsin, Madison, Wis.* The proteins of the blood serum and amniotic fluid of chick embryos have been studied as a function of time of incubation. No electrophoretic changes in the

residual egg white proteins are apparent in pH 8.6 diethylbarbiturate buffer of ionic strength 0.1. The proteins of the amniotic fluid from the 12-19th day of incubation gave patterns identical with those of the egg white proteins. Analyses of the blood serum of embryos, age 10-19 days, revealed marked changes. On the 13th day of incubation the serum contains 102 mg % protein nitrogen and 8.3 mg % lipid phosphorus. A large amount of the protein possesses an electrophoretic mobility higher than that of the serum albumin. These faster migrating proteins carry the lipid phosphorus as evidenced by analyses of electrophoretically isolated material and correlating sedimentation studies. By the 19th day of incubation they are present in much lower concentration. Simultaneously the lipid phosphorus appears with slower migrating proteins. Sedimentation analyses of embryo serum in sodium chloride solutions of varying density shows the presence of at least 3 molecular components.

Metabolism of dehydroisoandrosterone in a woman before and after removal of an adrenocortical tumor. HAROLD L. MASON, JOHN J. SCHNEIDER (by invitation) and EDWIN J. KEPLER (by invitation). *Division of Biochemistry and Division of Medicine, Mayo Clinic, Rochester, Minn.* Dehydroisoandrosterone acetate (150 mg/day for 8 days) was administered to a woman with a virilizing adrenocortical tumor. The daily amount of 17-ketosteroids excreted increased from an average of 258 to 274 mg, and the proportion of the β -fraction did not change. After removal of the tumor, administration of the same amount of dehydroisoandrosterone acetate increased the excretion of 17-ketosteroids from 2.8 to 52.3 mg/day (average). The β -fraction increased progressively to 38 and 36 per cent of the total 17-ketosteroids on the 7th and 8th days. Androsterone, dehydroisoandrosterone, etiocholan-3(α)-ol-17-one, 3-chlorodehydroandrosterone, Δ^6 androstene-3(β), 17(α)-diol, pregnane-3(α), 20(α)-diol and a new alcohol, $C_{21}H_{34}O$, were isolated from the urine during a control period, and during the first period of administration of dehydroisoandrosterone acetate. The quantitative relations of these compounds were essentially the same in the 2 periods. During the period after operation, androsterone, dehydroisoandrosterone, etiocholan-3(α)-ol-17-one and pregnanediol were isolated. It was expected that administration of an amount of dehydroisoandrosterone comparable to the amount being excreted would affect the relations of the various urinary steroids, and that perhaps most of the dehydroisoandrosterone would be excreted unchanged. The only effect, however, was a small increase in the total amount of 17-ketosteroids. After operation considerable dehydroisoandrosterone was recovered from the urine, and androsterone and etiocholanolone were isolated in amounts (43 and 32 mg, respectively) which were

considerably greater than the total of the endogenous 17-ketosteroids. This last result is in accord with the conclusion that dehydroisoandrosterone normally is converted largely to androsterone and etiocholanolone before excretion.

Manometric determination of methyl alcohol in blood. M. F. MASON, *Parkland Hospital and Southwestern Medical College, Dallas, Texas.* Methyl alcohol, alone or in the presence of ethyl alcohol, in blood may be determined with accuracy sufficient for forensic purposes by the following manometric procedure which is independent of standardized reagents. The distillate obtained from 10 cc or 20 cc of tungstate filtrate in the Harger method for blood alcohol (*J. Lab. Clin. Med.* 20: 746, 1935) is made to 25 cc. Apparatus 'C' described by Van Slyke *et al.* (*J. Biol. Chem.* 141: 627, 1941) for determining carboxyl- CO_2 is modified by introduction of a side arm equipped with a stop-cock and cup at the shoulder of the tube. Silicone lubricant is used sparingly in the stop-cocks, phosphoric acid as a joint seal. Five cc of a bichromate-sulfuric acid mixture (e.g. Anstie's reagent) are placed in the tube and the apparatus evacuated (water pump) several times with shaking. Five cc of distillate and 0.5 cc of water for washing are admitted via the cup without loss of vacuum, the apparatus shaken, and boiled for 10 minutes. After cooling to about 45°C the apparatus is connected to the chamber of the Van Slyke-Neill manometric analyzer and the CO_2 evolved is determined as described by Van Slyke *et al.* (*vide supra*). The blank is determined on acidified, boiled water, treated similarly. Methyl alcohol is calculated from the CO_2 determined. Recoveries of added methyl alcohol with or without ethyl alcohol ranged from 97 to 100%. In interpreting results the specificity features of the bichromate oxidation should be kept in mind.

Preliminary communication on the effect of growth hormone on tissue enzymes. JAMES C. MATHIS (introduced by OLIVER H. GAEBLER), *Edsel B. Ford Institute for Medical Research, Henry Ford Hospital, Detroit, Mich.* Growth hormone might promote nitrogen storage by reducing amino acid deamination, or by increasing reutilization of D-amino acids, therefore its effect on D-amino acid oxidase activity was investigated. The oxidase was assayed according to Axelrod *et al.* (*J. Biol. Chem.*, 134: 749, 1940), but a pyrophosphate buffer of pH 8.3 was employed. *In vitro* experiments involving five different oxidase sources and various pH values showed growth preparations to be without effect. Growth hormone also did not counteract the oxidase inhibitor effect. Experiments on the intact rat, using two strains, several levels of hormone treatment, groups of both sexes, with both *ad libitum* and paired feeding were performed. The data for one representative series

follow Five 'plateaued' Sprague-Dawley female rats were given 6 mg hormone intraperitoneally per day for 7 days and 12 mg on the 8th day, following which they and their pair-fed controls were killed for enzyme assay. Oxidase activities, and standard deviations, are given in cmm oxygen uptake per organ/hr/100 gm final body weight. The essentially constant enzyme activity would indicate that no specific activating or deactivating relationship exists between the hormone and the

Organ	Controls	Treated
Kidney	-1170 \pm 740	-1220 \pm 170
Liver	-730 \pm 470	-1100 \pm 490

oxidase. The total amount of functioning enzyme in the liver appears roughly equal to that in the kidney. Effects of growth preparations on other enzyme systems will also be discussed.

Formazyl color reaction as a possible biochemical analytical tool. NORMAN L. MATTHEWS (introduced by EARL R. NORRIS) *Dept of Pharmacology, Univ of Washington, Seattle, Wash, Emory Univ School of Medicine, Emory University, Ga, and Univ of Rochester School of Medicine and Dentistry, Rochester, N Y*. Although the formazyls were well known in the older literature, apparently no attempt has been made to use the formation of these highly colored substances for analytical purposes. The following classification serves to indicate the possible wide range of application of the formazyls in this respect. I. Substances which yield formazyls by direct reaction with benzene diazonium salts in a) mild acid medium (oxalacetic, acetoacetic, and malonic acids) and b) only alkaline medium (pyruvic acid, acetaldehyde, acetone, etc.), II. Substances whose phenylhydrazones yield formazyls when reacted with diazonium salts in alkaline medium (aldehydes, aldose sugars, and certain α -ketoacids). Formazyls apparently have not been prepared from aldoses, and only formazyl itself could be isolated from the reaction mixture when mannose phenylhydrazone and glucose phenylhydrazone were studied. The advantages of the formazyls as possible analytical agents are that they are easily formed, the sensitivity is great and the colors are characteristic. Disadvantages are that a mixture of formazyls is often formed from one compound, the reaction is not specific, and there is a certain amount of blank color. Quantitative studies have been made with glucose. It was found possible to achieve excellent color development by simply treating with iodine a solution prepared by adding NaOH to a briefly heated mixture of the glucose sample and buffered phenylhydrazine solution. With proper conditions it is possible to minimize the blank color, quantitate the amount of color

with the amount of glucose and limit the effect of interfering substances.

Deamination of crystalline egg albumin. PAUL MAURER (by invitation) and MICHAEL HEIDELBERGER *Depts of Biochemistry and Medicine, College of Physicians and Surgeons, Columbia University, New York City*. Water solutions of crystalline egg albumin (Ea) were treated at 0-2°C in acetate buffer with NaNO₂ at pH 4.0 for varying periods. The mixtures were neutralized, dialyzed nitrite-free, and were treated with thioglycollic acid at pH 7.5 to reduce any -S-S- linkages formed. After dialysis to remove thioglycollate, two fractions were separated at the pH of maximum insolubility, 3.9 to 4.0, one soluble, the other insoluble. Both fractions gave homogeneous electrophoretic and diffusion patterns. The soluble fraction was homogeneous in the ultracentrifuge and showed the properties to be expected of an undenatured, partly deaminated Ea. Complete deamination was not achieved under the mild conditions used. In spite of the care taken, the insoluble fraction, which increased with time of exposure to the deaminating solution, was denatured as shown by its insolubility at the isoelectric point and other physical properties and by its chemical and immunological reactions. Data are presented on the percentage of deamination, viscosity, $[\alpha]_D$, and cross reactivity of each fraction with calibrated anti-Ea and anti-denatured Ea sera.

Depolymerase activities of calf spleen and thymus cathepsin preparations. MARY E. MAVER and ANTOINETTE GRECO (by invitation) *National Cancer Institute, Bethesda, Md*. In a study of the role of cathepsins in nuclear metabolism it was found that these intracellular proteinases from calf thymus and calf spleen hydrolyzed thymus nucleoproteins and rendered the nucleic acid dialyzable. This dipolymerizing function of the cathepsin preparations differed from that of the pancreatic dipolymerases in showing optimal activity at pH 4.5 for both the desoxyribonucleic acid (DNA) and ribonucleic acid (RNA). In view of the close association of proteolytic activity with the crystalline depolymerases of the pancreas the correlation of proteinase activity with the dipolymerase activity of the cathepsins is of interest. The spleen enzymes which show the highest catheptic activity of any tissue studied show the greatest depolymerase activity. The same activators and inhibitors which affect the catheptic activities of these enzymes also affected their depolymerase activities. The proteinase activity of the calf spleen cathepsin was found previously to be sensitive to the sulfhydryl reagent, *p*-chloromercuribenzoate. The *K* value of 22×10^{-3} for the first order reaction in the depolymerization of DNA as determined by viscosity measurements was reduced 48% by the addition of 2.5 micromoles

of *p*-chloromercuribenzoate per mg enzyme. The same reagent decreased the amount of soluble phosphorus liberated from both DNA and RNA. No inorganic phosphorus was liberated by the cathepsins. Cysteine caused a definite increase in the rate of depolymerization of DNA and in the amount of soluble phosphorus liberated.

Hepato-renal factors in circulatory homeostasis

XXI Quantitative immunochemistry of ferritin and apoferritin ABRAHAM MAZUR and EPHRAIM SHORR (by invitation) *Dept of Medicine, Cornell Univ Medical College and The New York Hospital, New York City*. During a study which resulted in the identification of ferritin as the hepatic vasodepressor, VDM, which is concerned with the regulation of the peripheral circulation (*J Biol Chem*, 176: 771, 1948), the immunochemical behavior of ferritin and its iron-free protein moiety, apoferritin, was investigated. Using the quantitative-precipitin technique, it was shown that horse liver and spleen ferritin are identical. Similar immunochemical identity was established for horse ferritin and apoferritin. The iron in the specific precipitates accounted quantitatively for all of the antigen added in the region of excess antibody and up to the end of the equivalence zone. Thus, in these zones, the antibody N in the precipitate may be calculated by subtracting the added antigen N from the total N of the precipitate. Calculation of the molar ratios of rabbit serum antibody (\bar{M} 150,000) to apoferritin (\bar{M} 465,000) gave values corresponding to the formulae, Ab_1Apo in the zone of extreme antibody excess, $Ab_{1.4}Apo$ at the antibody excess end of the equivalence zone and Ab_7Apo at the antigen excess end of the equivalence zone. Inhibition of precipitation was observed with large excess of antigen. By the micro precipitin technique, using the Folin color reagent to estimate the precipitated protein, 1 to 2 gamma ferritin N could be determined. By means of the complement-fixation test, 0.05 gamma ferritin N was detected. Immunochemical cross reactions were obtained between horse and dog ferritins and to a lesser extent between horse and human ferritins.

Hepato-renal factors in circulatory homeostasis **XXII Chemical properties of ferritin and apoferritin** ABRAHAM MAZUR and EPHRAIM SHORR (by invitation) *Dept of Medicine, Cornell Univ Medical College and The New York Hospital, New York City*. The identity of ferritin with the hepatic vasodepressor, VDM, which is concerned with the regulation of the peripheral circulation (*J Biol Chem*, 176: 771, 1948) led to a study of some chemical characteristics of ferritin and its iron-free protein moiety, apoferritin. Fractionation with varying concentrations of $(NH_4)_2SO_4$ yielded preparations with widely differing Fe

content. The original ferritin contained 1.88 mg Fe/mg N. The fraction precipitated at 23% saturated $(NH_4)_2SO_4$ had 2.20 mg Fe/mg N, whereas that precipitated between 40-50% saturated $(NH_4)_2SO_4$ had 0.55 mg Fe/mg N. All fractions gave typical crystals with $CdSO_4$. The ration of Fe/P in all fractions as constant. A similar fractionation was obtained by centrifuging a ferritin solution at 13,000 rpm. Electrophoresis studies with ferritin and apoferritin yielded identical mobilities at pH values from 3.95 to 8.6. An approximate isoelectric point of 4.4 was thus obtained. Amino acid analyses of apoferritin and ferritin yielded identical values for both on the basis of N content. Some amino acid values for apoferritin were (in %) glutamic (17.0), leucine (19.1), arginine (9.0), lysine (7.5), histidine (4.8), phenylalanine (5.9), tyrosine (4.8), valine (4.3), cystine (1.7), methionine (1.8). The total S of apoferritin (0.89%) was accounted for by cystine and methionine. The action of crystalline pepsin and trypsin on ferritin and apoferritin was also studied.

Comparison of the electrophoretic components of human serum at pH 4.5 and 8.4 JOHN W. MEHL, FLORENCE GOLDEN (by invitation), and JANE HUMPHREY (by invitation) *Dept of Biochemistry and Nutrition, University of Southern California School of Medicine, and the Los Angeles County General Hospital, Los Angeles, Calif*. At a pH of 4.5, two components with isoelectric points below those of serum albumin may be distinguished. One of these has been identified as a mucoprotein, and has been found to increase in cancer, pneumonia, and a number of other conditions. This component contributes to the α globulin fraction at pH 8.4. The other acid component is also increased in conditions in which the most acid fraction is increased, and may be also a mucoprotein. Three globulin fractions are obtained at pH 4.5, one of which can be identified with γ -globulin, and a second with β globulin. The third component must be made up of part of the α -globulin indicated by electrophoresis at pH 8.4. The quantitative relations between the components observed at pH 4.5 and pH 8.4 will be discussed, and possible applications to the study of pathological sera considered.

Metabolism of 2,4- and 3,5-diketo acids ALTON MEISTER (introduced by JESSE P. GREENSTEIN) *National Cancer Institute, Bethesda, Md*. The enzymatic hydrolysis of 2,4-diketo acids yielding pyruvic and fatty acids, which was previously reported, may be followed by an ultraviolet absorption technique. Such a procedure was employed in following the metabolism of 3,5-diketohexanoic acid and its δ -lactone. The lactone was enzymatically converted to free 3,5-diketohexanoic acid and the free acid was hydrolyzed to yield aceto-

acetic and acetic acids by homogenates of rat liver and kidney. Lactonase activity was associated with the sedimentable fraction of liver homogenate and had a pH optimum at about 6, while the activity toward 2,4- and 3,5-diketo acids remained in the supernatant after high speed centrifugation. The pH optimum for hydrolysis of 2,4- and 3,5-diketoheptanoic acids was 7.3 to 7.9. Hydrolysis of 2,4- and of 3,5-diketo acids are analogous in that both reactions involve splitting of a C-acyl group. 2,4-diketoheptanoic acid was hydrolyzed 11 to 14 times more rapidly than was 3,5-diketoheptanoic acid by liver and kidney of several species, by mouse hepatoma, and by partially purified enzyme preparations. Under conditions where n-hexanoic, β -ketoheptanoic, and 2,4-hexadienoic acids were oxidized rapidly by a sedimentable fraction of rat liver fortified as described by Lehninger, both 2,4- and 3,5-diketoheptanoic acids were metabolized at negligible rates. This suggests that these polyketo acids as such are not intermediates in the oxidation of n-hexanoic acid in this system, but are probably involved in other metabolic pathways.

Synthesis and microbiological testing of some alpha-aminosulfonic acids. JULIUS MENDEL and DONALD W. VISSER (introduced by HARRY J. DELEZ, JR.) *Dept. of Biochemistry and Nutrition, Univ. of Southern California School of Medicine, Los Angeles, Calif.* Several alpha-aminosulfonic acids have been prepared which competitively inhibit the naturally-occurring alpha-aminocarboxylic acids. McIlwain has reported considerable overlapping in the growth-inhibiting ability of the aliphatic alpha-aminocarboxylic acids. It was of interest, therefore, to synthesize an aliphatic aminosulfonic acid having no structural analog among the naturally-occurring amino acids. Alpha-aminopropanesulfonic acid and alpha-amino-beta-bromobutanesulfonic acid were synthesized by the addition of ammonium bisulfite to a slight excess of the appropriate aldehyde. The alpha-aminopropanesulfonic acid was antagonistic toward *Lactobacillus casei* at levels from 10^{-2} to 10^{-4} M. Slight reversal of antagonism was observed in the presence of alpha-aminobutyric acid, but no reversal of growth occurred with any of the other amino acids or mixtures of amino acids. Alpha-amino-beta-bromobutanesulfonic acid inhibited the growth of *Lactobacillus casei* completely at 10^{-4} M concentration.

Quantitation of the growth-retarding and anemia-producing effects of hexahomoserine. E. T. MERTZ, R. H. WALTZ, JR., D. C. SHELTON, L. P. DOYLE, and A. L. DELEZ (introduced by F. W. QUACKENBUSH) *Dept. of Agricultural Chemistry and Veterinary Science, Purdue University, Lafayette, Ind.* Young white rats were divided into groups of 6 and maintained for 28 days on a basal diet containing zein, tryptophan, histidine, and

2% DL-lysine HCl. Each group received, in addition to the basal diet, a different level of DL-hexahomoserine (α -amino, ϵ -hydroxy caproic acid). When the diet contained 0.08% to 0.33 DL-hexahomoserine, the growth rate was retarded without the simultaneous development of anemia. When the diet contained 1% DL-hexahomoserine, the growth rate was either retarded or reduced to zero, and the animals developed anemia. The rats were autopsied at the end of the experiment, and the autopsy findings will be discussed.

Electrometric method for the determination of red blood cell and plasma cholinesterase activity. HARRY O. MICHEL (introduced by WILLIAM H. SUMMERSON) *Biochemistry Section, Medical Div., Army Chemical Center, Md.* Red blood cell and plasma cholinesterase activity is determined in terms of the change in pH produced at 25° by the action of the enzyme on acetylcholine in a standard veronal-phosphate buffer, initially at pH 8.00. The pH change is measured with the glass electrode, and the reaction time is 1-1½ hours. Separate buffer solutions are used for red cells and plasma, the capacity of the buffers is such that relatively large variation in buffer capacity of added red cells or plasma do not affect results, and the decrease in enzymatic activity with decrease in pH is compensated for by an equivalent decrease in buffer capacity over the same range. Small correction factors are provided for non-enzymatic hydrolysis and for slight deviation in rate of pH change with pH. Only 1 ml. of a 1:50 dilution of plasma or hemolyzed red cells is required for a determination. The method compares favorably with the standard manometric procedure, and is much more suitable for routine use.

Metabolic conversion of the carbon chain of DL-lysine- ϵ -C¹⁴ to L-arginine in the dog. LEON L. MILLER *Dept. of Radiation Biology, Univ. of Rochester, School of Medicine and Dentistry, Rochester, N. Y.* DL-Lysine- ϵ -C¹⁴ (2.00 gm, 1.24×10^3 disintegrations/min) was fed mixed with meat protein to a normal dog. The dog was killed with perfusion 24 hours later. Tissue and blood proteins were hydrolyzed with 20% HCl, and the basic amino acids separated with the ion exchanger Amberlite IRC-50. L-Arginine was isolated as the monofluoride, after several reprecipitations from

	C ¹⁴ DISINTEGRATION/MINUTE/MILLIMOL $\times 10^{-4}$			
	Arginine mono- fluoride	Guanidi- nium moiety	Ornithine moiety	Glutamic acid
Liver	0.329	0.13	0.19	0.750
Plasma protein	0.323	0.15	0.13	0.60

solution containing added inert L-lysine. Failed to change its activity. The fluoride was used.

such and a portion decomposed with barium hydroxide. The arginine was converted to ornithine, carbon dioxide and ammonia by further treatment with baryta in a sealed tube. Ornithine was isolated as a diparatoluenesulfonyl derivative which was assayed as such. The ornithine moiety contained about 50% of the activity present in the arginine flavanate. The rest of the activity was found in the CO_2 of the guanidine moiety. The activity of glutamic acid isolated from the same tissues is included for comparison. Because the glutamic acid had only about 4 times the activity of the ornithine, it seems more likely that both were derived from a common precursor, rather than that ornithine is derived from glutamic acid through several intermediates postulated by others for such a conversion.

Metabolic conversion of the carbon chain of DL-Lysine- $\epsilon\text{-}^{14}\text{C}$ to L-glutamic and L-aspartic acids in the dog. LEON L. MILLER and WILLIAM F. BALE (by invitation). *Dept. of Radiation Biology, Univ. of Rochester School of Medicine and Dentistry, Rochester, N. Y.* DL-Lysine- $\epsilon\text{-}^{14}\text{C}$ (2.00 gm with 1.24×10^8 disintegrations/min) was fed with meat protein to a normal dog. When killed 24 hours later, approximately $\frac{1}{3}$ of the activity had appeared in the expired CO_2 , $\frac{1}{3}$ in the urine and the rest incorporated in tissue and blood proteins. The proteins were hydrolyzed with 20% HCl, and the dicarboxylic amino acids separated with the ion exchanger Amberlite IR-4. Glutamic acid was isolated as the hydrochloride and aspartic acid as the copper salt. Paper partition chromatography was used routinely to control the separations and as an added criterion of purity of isolated amino acids. No evidence for the occurrence of α -amino-adipic acid was found. The most likely interpretation of the data must postulate more or less direct conversion of the carbon chain of lysine to that of glutamic acid by a hitherto unrecognized mechanism.

Podophyllotoxin on enzymes and tissue metabolism. ZELMA BAKER MILLER, CLARKE DAVISON (by invitation) and PAUL K. SMITH. *Dept. of Pharmacology, George Washington Univ. School of Medicine, Washington, D. C.* Podophyllotoxin, a carcinoclastic agent from podophyllin, was investigated against various metabolic systems. Oxygen uptake of rat kidney slices is progressively inhibited by 10^{-3}M podophyllotoxin (74% at 3 hours). Podophyllotoxin at 10^{-4}M inhibits to a less degree. The inhibition is greater in the absence of added substrate than in the presence of alanine, pyruvate, succinate and glutamate. Acetate oxidation is inhibited. The oxygen uptake of rat brain and liver slices, and of rat testes is only slightly reduced. The respiration of whole 5-day chick embryo is inhibited in the absence of, but not in the presence of, glucose. Oxygen uptake is stim-

ulated by podophyllotoxin below 10^{-3}M . Anaerobic glycolysis of 5-day chick embryo is inhibited 30-60% by 10^{-3}M podophyllotoxin, that of rat testes is inhibited 40-75%. Stimulation is sometimes observed at lower concentrations. Rat brain glycolysis is not affected. Carbohydrate synthesis from kidney slices and pyruvate is inhibited 40% by 10^{-3}M podophyllotoxin. Acetate and butyrate, but not glucose, oxidation by rabbit kidney homogenates is markedly inhibited by 10^{-3}M podophyllotoxin. Succinoylase (pigeon breast), choline and hypoxanthine oxidases (liver), choline esterase (brain), leucine oxidase (*Proteus vulgaris*), adenosine triphosphatase (liver), serum acid and alkaline phosphatase, ribonuclease (spleen), and thymonucleodepolymerase (dog serum) are not affected by this concentration. The viscosity of highly purified thymonucleic acid is not decreased by 30^{-3}M podophyllotoxin.

Prolamines treated with nitrogen trichloride. III. Sulfated zein. FERNANDA MISANI (by invitation), PHILIP WEISS (by invitation), M. G. CORNASCO (by invitation), T. W. FAIR (by invitation), and L. REINER. *Research Laboratories of Wallace & Tiernan Products, Inc., Belleville, N. J.* The NCl_3 -treated zein was sulfated according to the procedure of Reitz *et al.* (*J. A. C. S.* 68: 1024). The resulting product contained 1.9% sulfate sulfur and was soluble in water at neutral pH values. It possessed the typical fit producing toxicity of the parent compound. If zein was first sulfated and then treated with NCl_3 , a non-toxic product resulted. The NCl_3 consumption by sulfated zein was at least as great as that of the native zein. It appears that sulfation blocked in some manner the reactive group. Sulfamation is hardly responsible for the blocking effect since it has been shown previously that $-\text{NH}_2$ groups are not involved in the toxigenic reaction. Esterification of $-\text{OH}$ and $-\text{SH}$ groups, sulfonation and denaturation through dehydration might have occurred. One of the groups involved in these reactions must also be involved in the production of a toxic residue through reaction with NCl_3 .

Glycogen content of the liver of fasted alloxan diabetic rats. YOSHIKAZU MORITA (by invitation) and JAMES M. ORTEN. *Dept. of Physiological Chemistry, Wayne Univ. College of Medicine, Detroit, Mich.* In the course of investigations on the effect of inorganic and organic phosphate upon the glucose utilization of alloxan diabetic rats, it became necessary to determine the liver glycogen levels in fasting diabetic animals. A survey of the literature showed little information on this question. Male Sprague-Dawley rats, 150-250 gm in weight were rendered diabetic by injecting alloxan. Liver glycogen and blood sugar levels were determined on 24-hour and 48-hour fasted animals, and the results compared with values found

in normal controls Twenty rats were used in each group In the 24-hour fasted animals, the diabetic group averaged $2.15 \text{ gm} \pm 0.277$ (the standard error of the mean) per 100 gm of liver, while the normals averaged $0.324 \pm 0.053 \text{ gm} \%$, a highly significant difference In the 48-hour fasted group, the diabetic animals showed $0.679 \pm 0.090 \text{ gm} \%$, also a highly significant difference The fasting blood sugar for the 24-hour fasted group of diabetic animals averaged $153 \pm 22 \text{ mg} \%$, for the 48-hour fasted animals, $90 \pm 7 \text{ mg} \%$ The blood sugar values for the control group of rats were within the normal range ($55\text{--}90 \text{ mg} \%$) Studies on the effect of inorganic phosphate and hexose phosphate on the glycogen content of the liver in the alloxan diabetic rat are now in progress

Position of the oxygen dissociation curve in cyanotic congenital heart disease MINERVA MORSE, DONALD E CASSELS (by invitation) and MELBA HOLDER (by invitation) *Dept of Pediatrics, Univ of Chicago, Chicago, Ill* In spite of decreased arterial oxygen saturation, the arterial oxygen content in cyanotic congenital heart disease is usually as high or higher than normal because of a compensating polycythemia It is possible, however, that the tissues suffer anoxia due to the low oxygen tension associated with lowered saturation The position of the oxygen dissociation curve has been examined to determine whether the affinity of hemoglobin for oxygen has been altered by compensatory processes in such individuals Data were derived from Van Slyke analyses of blood samples equilibrated at 37°C with gas mixtures containing approximately 5% CO_2 and different tensions of O_2 Data were corrected to a pH of 7.1 As a control corresponding data were determined for normal individuals The position of the O_2 dissociation curve for healthy young adult males as determined by us was found to differ somewhat from reports in the literature Furthermore the curve for normal children lay to the right of that for adult males Positions of the curve for patients with cyanotic congenital heart disease, compared with those of normal individuals of approximately the same age, indicate a trend toward the right, i e, toward decreased affinity of hemoglobin for oxygen This is more marked in adults than in children, and is especially marked in cases complicated by pulmonary stenosis This is interpreted as an adaptation to increase the oxygen tension of the tissues

Hemostatic effects of normal blood transfusions in hemophilia-like swine M E MUHRER (introduced by A G HOGAN) *Depts of Agricultural Chemistry and Animal Husbandry, University of Missouri, Columbia, Mo* Evidence has been accumulated to show that the hemophilia-like swine at the Missouri Experiment Station have a blood vessel defect in addition to the previously ob-

served coagulation defect A number of treatments have been effective in reducing the coagulation time to near the normal level but these treatments have not been effective in reducing the prolonged saline bleeding time The injection of hemolytic agents or hemolyzed cells will sharply lower the coagulation time but has no effect upon the saline bleeding time An intravenous injection of 5–50 ml of normal blood in a 50-pound bleeder pig lowers the coagulation time but the bleeding time of over 600 seconds is not affected However, if the amount of normal swine blood transfused into a 50-pound bleeder animal is increased to 500 ml both the coagulation time and saline bleeding time are lowered Ten animals ranging from 13 pounds–140 pounds in weight were given transfusions ranging from 175 ml–1000 ml All animals had a saline bleeding time of more than 600 seconds before transfusion and an average of 195 seconds after transfusion It appears that there are two blood factors involved in the hemostatic defect in hemophilia-like swine, one that affects coagulation time and another that affects bleeding time If there is a capillary defect, as is usually postulated with prolonged bleeding times, then the capillaries may be affected by the blood that is flowing through them and failure of the capillaries to constrict could be caused by a blood defect

Relation of the electrolyte compositions of serum and skeletal muscle EDWARD MUNTWYLER, GRACE E GRIFFIN (by invitation), GEORGE S SAMUELSEN (by invitation) and LOIS E GRIFFITH (by invitation) *Dept of Biochemistry, Long Island College of Medicine, Brooklyn, N Y* The electrolyte content of the serum and skeletal muscle was determined in rats and dogs maintained on diets deficient in potassium, and following repeated injections of desoxycorticosterone acetate In rats, the loss of skeletal muscle potassium and gain of intracellular sodium was found to be accompanied by an increased serum bicarbonate and a lowered serum chloride concentration These observations are in agreement with those reported recently by Darrow, *et al* (*J Clin Invest* 27:198, 1948) In the present experiments the change in the composition of the muscle with respect to potassium and sodium was generally found to be less pronounced in dogs than in rats Dogs with a deficit of muscle potassium and gain of intracellular sodium failed to exhibit the large increase in the serum bicarbonate concentration observed in rats Similarly, there was a smaller decrease in the serum chloride concentration However, in certain experiments with dogs the serum bicarbonate concentration tended to be increased In these instances the serum chloride concentration appeared to show a relatively greater fall

New colorimetric reaction for the determination of epinephrine SAMUEL NATELSON and JOSEPH

B PINCUS (introduced by ALBERT E SOBEL) *Dept of Chemistry and Pediatrics, Jewish Hospital, Brooklyn 16, N Y* 100 μ g of epinephrine heated in a boiling water bath for twenty minutes with 3 ml of a 2% selenic acid solution in 1 N sulfuric acid will reduce the selenic acid to produce a pale blue color turning to yellow and then orange. An orange precipitate forms on standing. When this solution is cooled to room temperature and acid arsenomolybdate is added the molybdate blue develops in a few minutes. Acid Phosphotungstate and acid Phosphomolybdate will also produce blues but of lesser intensity. Glucose, Tryptophane, Glycine, Methionine and Tyrosine do not interfere in this procedure. Catechol gives the same reaction. The color read at 730 $m\mu$ in the Beckman Spectrophotometer yielded an $E_{1\%}^{1cm}$ of approximately 2000 at 730 $m\mu$ based on the amount of epinephrine present. If the color is developed in 1 ml and the micro cuvettes with a 1 cm light path are used the procedure is capable of determining 0.2 μ g of epinephrine.

Concentration of bound pantothenic acid J B NEILANDS (by invitation), HARVEY HIGGINS (by invitation), and F M STRONG *Dept of Biochemistry, College of Agriculture, Univ of Wisconsin, Madison, Wis*. The development of Lipmann's enzymatic method for liberation of pantothenic acid from coenzyme A preparations (*J Biol Chem*, 167: 869, 1947) offered a convenient guide for attempts to purify the bound (*i.e.* microbiologically unavailable) form of pantothenic acid present in certain fresh biological materials. Preliminary work with hog liver and fresh brewer's yeast involving hot water extraction, precipitation with 70% alcohol, and fractional precipitation with heavy metal salts led to preparations containing only about 0.1% pantothenic acid in the bound form. Better results were obtained when livers from freshly killed rabbits were homogenized with 0.9% KCl, and the easily sedimentable fraction ('cyclophorase', Green *et al*, *J Biol Chem*, 172: 389, 1948) was used as starting material. When this material was deproteinized with trichloroacetic acid, and precipitated with barium and alcohol, the precipitate contained 0.2-0.4% of bound pantothenic acid. Counter-current fractionation (Craig) of such concentrates with phenol and aqueous buffer solutions raised the purity to about 2%. This represents approximately a 150-200-fold concentration as compared to the original liver. Such preparations contain no detectable free pantothenic acid.

Effect of pH and temperature on carboxypeptidase activity HANS NEURATH and ELAINE ELKINS-KAUFMAN (by invitation) *Dept of Biochemistry, Duke Univ School of Medicine, Durham, N C*. Kinetic measurements of the hydrolysis of carbobenzoxyglycyl-L-phenylalanine by carbo-

xyptidase were carried out at pH 6.5, 7.5, 8.3 and 9.0, and at temperatures ranging from 9° to 32°. Hydrolysis rates were evaluated according to the two step reaction mechanism and were expressed in terms of K_m , the enzyme-substrate dissociation constant, and k' , the specific rate constant for the activation process (Elkins-Kaufman and Neurath, *J Biol Chem* 175: 893, 1948). K_m was minimal at pH 7.5 and increased about 5 fold between pH 7.5 and 6.5, and about 2 fold between pH 7.5 and 9.0. k' was constant between pH 7.5 and 8.3, with a sharp increase below and a moderate decrease above this range. The calculated maximum proteolytic coefficient was highest at pH 7.5. Measurements of the temperature effects at each pH were interpreted in terms of the classical thermodynamic constants, ΔH , ΔS and ΔF , for the equilibrium reaction (step 1) and in terms of the corresponding constants for the activation process (step 2), as previously described for chymotrypsin (Kaufman, Neurath and Schwert *J Biol Chem* 177, in press). ΔH decreased markedly with increasing pH. However, a compensatory decrease in ΔS , the entropy of the equilibrium reaction, rendered ΔF , the free energy change, nearly independent of pH (about 1,600 cal/mole). Similar relations were found for the corresponding thermodynamic constants of the activation process (ΔF^* about 15,000 cal/mole). The significance of these data is discussed.

Histochemical demonstration of three groups of alkaline (pH 9.2) phosphatases using various substrates and inhibitors WILLIAM NEWMAN (by invitation), IRWIN FLIGIN (by invitation), ABNER WOLF (by invitation), and ELVIN A. KABAT *Veteran's Hospital, Kingsbridge, Departments of Pathology and Neurology, Columbia University and the Neurological Institute, New York City*. The Gomori histochemical technique for localizing alkaline phosphatases was studied using glycerophosphate, glucose-1-phosphate, creatine phosphate, yeast nucleic and adenylic acids, thiaminepyrophosphate hexosediphosphate, muscle adenylic acid and adenosinetriphosphate as substrates and with various inhibitors. Three distinct groups of alkaline (pH 9.2) phosphatases were recognized. **Group I** enzymes were seen with all substrates in cytoplasm and nuclei of many organs, notably, intestine, renal tubules and adrenal cortex. Enzyme action is inhibited by heat, M/4 glycine or arginine and M/100 KCN, and corresponds largely with previous histochemical findings. Optimal **Group I** staining appeared with all substrates except thiaminepyrophosphate and yeast nucleic acid. **Group II** enzymes are demonstrated in cytoplasm of cells lacking **Group I** with muscle adenylic acid and adenosinetriphosphate, but not with yeast adenylic acid or other substrates, suggesting specificity for the purine-ribose-5-phosphate linkage. **Group**

II enzymes occur characteristically in cytoplasm and nuclei of smooth muscle and some connective tissues *Group III* enzymes occur in nuclei Muscle and yeast adenylic acids, creatine and glycerophosphates are more rapidly split than the other substrates, these differences in rates of hydrolysis permit recognition of *Group III* *Group II* and *III* enzymes are less affected by heat, glycine, arginine and KCN than are *Group I* facilitating differentiation Dialysates of autolyzed rat intestine and guinea pig kidney and adrenal enhance staining even with optimal Mg^{++} and inhibitory glycine concentrations

Effect of folic acid, liver extract and vitamin B_{12} on hemoglobin regeneration in chicks C A NICHOL (by invitation), A E HARPER (by invitation), L S DIETRICH (by invitation) and C A ELVEHJEM *Dept of Biochemistry, College of Agriculture, Univ of Wisconsin, Madison, Wis* No change in hemoglobin level accompanied the growth response of chicks to injection of anti-pernicious anemia liver extracts or vitamin B_{12} when a corn-soybean basal ration was fed However, chicks fed a folic acid deficient purified ration for 21 days developed a slight anemia If a single injection of phenylhydrazine hydrochloride (2 mg/100 gm body wt) was given at this time a severe anemia developed within two days Experimental treatments were then begun and hemoglobin levels were determined at 2- to 4-day intervals Injection of liver extract or vitamin B_{12} alone did not cause any significant hemoglobin response Folic acid alone produced a definite increase and pteroyl triglutamate and pteroyl heptaglutamate were equally as effective at equimolar dosage The combined administration of folic acid and liver extract or folic acid and vitamin B_{12} induced a more rapid regeneration of hemoglobin than treatment with folic acid alone The duration of the depletion period influenced this response After 14 days, treatment with folic acid and liver extract did not differ from treatment with folic acid alone After 21 or more days depletion, treatment with folic acid and liver extract consistently caused more rapid regeneration of hemoglobin than treatment with folic acid alone Chicks continued on a folic acid-deficient diet or on a diet containing vitamin B_{12} and low levels of folic acid developed a characteristic paralysis The response of these chicks to treatment with folic acid and related compounds will be reported

Protein and amino acid requirements of the German cockroach J L NOLAN (by invitation) and C A BACMAN *Dept of Biochemistry, College of Agriculture, Univ of Wisconsin, Madison, Wis* Cockroaches were fed semi synthetic diets containing various amounts and kinds of protein, and the rates of growth and maturation were determined The quantitative requirement for casein

was met at a level of 30% casein plus 30% bulk, or by 45% casein in the absence of bulk, indicating a relatively high requirement for dietary protein When various proteins were fed at 15% of the diet, fibrin was superior to casein, followed by lactalbumin, egg albumin, zein, gelatin, oxidized casein and amino acid mixtures, in decreasing order of effectiveness The 'incomplete' proteins zein, gelatin, and oxidized casein supported only slow growth, although some roaches fed these proteins reached maturity after a 30-fold increase in body weight Analyses of cockroaches which had been reared to maturity on diets containing oxidized casein revealed that normal amounts of tryptophane and methionine had nevertheless been formed, indicating the synthesis of these two 'essential' amino acids by the insect or by its associated microorganisms It was concluded from these experiments that the protein and amino acid requirements of the cockroach must be quantitatively and qualitatively different from the corresponding requirements of the rat and chick

Pteridines on hemapoiesis and cell proliferation EARL R NORRIS and JOHN J MAJNARICH (by invitation) *Dept of Biochemistry, Univ of Washington, Seattle, Wash* Using the technique previously described (*Am J Physiol* 152 179, 153 133, 1948), the effect of vitamin B_{12} , xanthopterin, folic acid and products of the action of enzymes, upon xanthopterin and folic acid, upon blood regeneration in rats made anemic on a purified diet containing 1% sulfathiazole, was measured The results obtained with xanthopterin and folic acid checked the results previously obtained Vitamin B_{12} , and the products of the action of enzymes upon xanthopterin and folic acid were much more effective in alleviating the anemia and leukopenia in the rats than were xanthopterin or folic acid The results obtained *in vivo* substantiated the results reported previously for cell culture *in vitro*, where vitamin B_{12} , and the products of the action of enzymes on xanthopterin and folic acid were shown to be more effective than xanthopterin or folic acid The effect of certain minerals upon the anemia will be discussed

Phosphatase activity in homogenates of liver and other organs of the rat ALEX B NOVIKOFF (introduced by HAROLD B PIERCE) *Dept of Pathology, Univ of Vermont College of Medicine, Burlington, Vt* Freshly prepared rat liver homogenates were assayed for phosphatase activity with a variety of substrates in a pH range of 4.0 to 9.1 The activity curves obtained fall clearly into 2 classes *Class I* includes yeast adenylic acid ($A-3P$) and 2 esters widely used in phosphatase determinations, sodium beta glycerophosphate, and disodium phenyl phosphate (ϕP) None of these is present in animal cells Activity is optimum at pH 5.5 low at pH 7.4 and very low at pH 9.1 *Class II*

includes esters of physiological significance adenosine triphosphate (ATP), muscle adenylic acid (A-5-P), glucose-6-phosphate (G-6-P), fructose 1,6 diphosphate (HDP), and glucose-1-phosphate (G-1-P). There is little activity at pH 5.0. At pH 9.1, there is high activity with ATP, A-5-P, and HDP, and low activity with G-6-P and G-1-P. Most significant is the very high activity obtained with all 5 of these esters at pH 7.4, which is presumably close to physiological. When tested with 2 esters from Class I (ϕ -P and A-3-P) and 2 from Class II (A-5-P and ATP), homogenates of spleen and kidney give essentially the same type of activity curves as liver does, with only the Class II esters being actively split at pH 7.4. However, kidney is highly active with all 4 substrates at pH 9.1. The pH activity curves of intestinal mucosa homogenates are strikingly different from those of the other organs tested. All 4 esters yield similar curves, and irrespective of whether they belong to Class I or II they are actively split at pH 7.4.

Enzymatic synthesis of l-malic acid by CO_2 fixation SEVERO OCHOA, J. B. VEIGA SALLES (by invitation), and PRISCILLA J. ORTIZ (by invitation) *Dept. of Pharmacology, New York University College of Medicine, New York City*. As previously reported (Ochoa, Mehler and Kornberg *J. Biol. Chem.*, 174: 979, 1948) the equilibrium of the reaction $\text{l-malate} + \text{TPN}_{\text{red}} \rightleftharpoons \text{pyruvate} + \text{CO}_2 + \text{TPN}_{\text{ox}}$, catalyzed by an enzyme isolated from pigeon liver, can be shifted toward CO_2 fixation by a dismutation with the glucose-6-phosphate dehydrogenase system. The overall reaction $\text{glucose-6-phosphate} + \text{pyruvate} + \text{CO}_2 = \text{6-phosphogluconate} + \text{l-malate}$ thus obtained, has been further studied with highly purified preparations of the pigeon liver enzyme. As with the tricarboxylic system (Ochoa, *J. Biol. Chem.*, 174: 133, 1948) the reaction can be followed manometrically through the liberation of CO_2 from bicarbonate by the phosphogluconic acid formed, since the disappearance of CO_2 by fixation is balanced by the formation of a carboxyl group of malic acid. l-Malate was determined with the enzyme system from *L. arabinosus* which specifically and quantitatively converts it to lactate and CO_2 (Korkes, and Ochoa, *J. Biol. Chem.*, 176: 463, 1948). The isolation and identification of l-malic acid will be described. The disappearance of glucose-6-phosphate and pyruvate was determined enzymatically with 'Zwischenferment' and lactic dehydrogenase respectively. The rate of malate synthesis is proportional to the CO_2 tension. By combination of the isocitric and malic enzyme systems one obtains the reversible reaction $\text{d-isocitrate} + \text{pyruvate} + \text{CO}_2 \rightleftharpoons \alpha\text{-ketoglutarate} + \text{CO}_2 + \text{l-malate}$. The equilibrium position of this reaction favors the formation of malate.

Extraction and estimation of desoxypentose

nucleic acid (DNA) and pentose nucleic acid (PNA) from plant tissues MAURICE OGUR and GLORIA ROSEN (introduced by H. G. ALBAUM) *Botanical Laboratories, Univ. of Pennsylvania, Philadelphia, Penna.* Pentosans and polyuronides in plant tissues invalidate the estimation of PNA by pentose assay. The use of the ultraviolet absorption at 260 m μ , for the estimation of the nucleic acids extracted from tissues, has been studied in this laboratory. Perchloric acid, which does not absorb significantly in the ultraviolet, is used to extract the nucleic acid constituents from the tissue residue. Our data indicate that prolonged contact in the cold with perchloric acid extracts PNA but not DNA from the plant tissue residue. Perchloric acid at elevated temperatures extracts both PNA and DNA. Root tip segments of rye and corn were homogenized in ethanol, centrifuged, and the tissue residue extracted with a mixture of alcohol and ether, and then with cold, dilute perchloric acid. Two alternate procedures were followed after these preliminary extractions: 1) The tissue residue was treated with hot perchloric acid. DNA was determined in the extract by the diphenylamine reaction and total nucleic acid by the ultraviolet absorption at 260 m μ . RNA was estimated by difference. 2) The tissue residue was treated with perchloric acid in the cold and RNA determined in the cold extract. The residue was now treated with hot perchloric acid and the DNA determined. All fractions were examined by photocolometric estimation of: 1) total and inorganic phosphorus 2) total nitrogen 3) pentose 4) desoxypentose 5) ultra-violet absorption at 260 m μ .

Effect of biotin and choline intakes on liver storage of ingested cholesterol RUTH OKEY, ELEANOR RISSER VERNON (by invitation), S. LEFKOVSKI and R. PENCHARZ (by invitation) *Dept. of Home Economics and the Division of Poultry Research, Univ. of California, Berkeley, Calif.* To test the effect on liver cholesterol storage of varying choline and biotin intakes 250 young rats were given biotin deficient diets with and without 1% cholesterol. Protein content of the diets (about 20%) total lipid, salts and vitamin supplements other than choline, biotin, and for one group, inositol, were kept constant and adequate for growth. One diet contained egg white and another whole egg. One third of each group received no biotin, one a borderline supplement and the last an ample amount. Subgroups of the egg white series were given choline in amounts furnishing respectively 0.10 mg, 0.25 mg, 0.50 mg and 1.0 mg/gm of diet. The whole egg diet furnished about 7 mg choline/gr diet. Rats were killed after 7 to 9 weeks on diet. None of them showed kidney damage. In the egg white-fed animals given ample biotin or placed on diet after biotin storage (at 80-90 gm) decreases in liver cholesterol with the increases in

choline intake noted above were slight and inconsistent. Egg white fed rats placed on diet at 45 gm and allowed to develop borderline biotin deficiency stored maximum liver cholesterol (about 1.6%) with 0.5 mg choline and 0.5 mg inositol/gm diet. One group of rats given 0.1 mg choline/gm diet stored less than half this amount. Without added biotin liver cholesterol of rats fed whole egg were as low as 0.3%, with ample biotin supplements they reached 1.7% in the same time.

Acetate metabolism and ergosterol synthesis in *Neurospora* R. C. OTTKE (by invitation), E. L. TATUM and S. SIMMONDS, *Dept. of Microbiology, Yale Univ., New Haven, Conn., and Dept. of Biology, Stanford Univ., Calif.* Ergosterol has been identified as the principal sterol of *Neurospora*. The incorporation of deuterioacetate into mold mycelium, fat, and sterol has been followed using the wild-type strain and a mutant strain (Y-2492), which requires acetate for growth. Since considerably more deuterium is incorporated in the mutant than in wild-type grown under similar conditions, the results support the conclusions obtained from growth experiments (Tatum and Garnjobst, unpublished) and indicate that the mutant, in contrast to wild-type, is unable to form acetate from sugar. The results also show that acetate is incorporated in increasing proportions in *Neurospora* mycelium (about 3%), fat (about 10%), and in ergosterol (about 20%). Thus acetate metabolism in the mold appears to resemble closely that in the rat as shown by Bloch and Rittenberg. In an attempt to determine the location of the incorporated deuterium in the sterol molecule, infra-red absorption spectra have been obtained for the deuterated ergosterol. The spectra of ergosterol isolated from *Neurospora* grown on deuterioacetate and on normal acetate in heavy water show distinct and different absorption peaks, the former sample at 2225 cm^{-1} and the latter at 2190 cm^{-1} . Neither peak is shown by normal ergosterol. Although there is some uncertainty in the interpretation of the infra-red spectra, the location of these absorption peaks suggests that deuterium given as acetate may appear on the more unsaturated carbon atoms in ergosterol and that given as heavy water may appear at more saturated centers, i.e. methyl and methylene carbons.

Electrophoretic studies of the proteins of plasma and ascitic fluid in cirrhosis W. D. PAUL (by invitation), J. D. GORDON (by invitation), ROBERT L. DRYER (by invitation) and JOSEPH I. ROUTH, *Depts. of Medicine and Biochemistry, College of Medicine, State Univ. of Iowa, Iowa City, Iowa*. Marked deviation from the normal plasma protein distribution is an outstanding feature of cirrhosis of the liver. The lowered total protein and inverted A/G ratio is often accompanied by formation of protein-rich ascites. We have determined by

electrophoresis the protein components of simultaneously collected samples of plasma and ascitic fluid taken from several patients over intervals of time ranging from 7 weeks to 6 months. The results show a close qualitative similarity between any plasma sample and the corresponding ascites sample, which is perhaps produced by the dynamic equilibria between the blood and the transudate. Certain quantitative differences are also evident. In every case the ascitic fluid is richer than the plasma in albumin, α_1 -globulin and γ -globulin, while the plasma was richer than the fluid in α_2 -globulin, β -globulin, and fibrinogen. The best available estimates of the molecular weights of the various protein fractions show they increase in the order albumin, γ -globulin, α_1 -globulin, α_2 -globulin, fibrinogen, and β -globulin. These values indicate that possibly the selective protein enrichment of ascitic fluid may be directly related to the molecular weight of the protein components, and that in cirrhosis altered vascular permeability may be as important as altered protein synthesis.

Metabolism of alpha-estradiol in vitro W. H. PEARLMAN and R. H. DEMEIO (by invitation), *Dept. of Biochemistry, Jefferson Medical College, Philadelphia, Penna.* Alpha-estradiol-17-hemisuccinate as dissolved in a Krebs-phosphate medium buffered at pH 7.4 and incubated with rat liver slices at 37° for 4 hours. The ratio of hormone to liver tissue was approximately 1 to 500 parts by weight, in all, 845 mg of alpha-estradiol (as succinate) were used. On extraction and fractionation of the incubation mixture, 54 mg of crude crystalline estrone and 329 mg of crude crystalline alpha-estradiol were obtained. These crystalline products were purified, estrone was further identified by C,H analysis of the acetyl derivative. An unsuccessful search was made for beta-estradiol. Although an appreciable amount of strongly acidic phenols were obtained, this material yielded no crystalline fractions on chromatography. Most of the estradiol succinate had undergone hydrolysis during incubation and very little if any of the hormone had been conjugated (e.g. as sulfate or glucuronide). Evidently alpha-estradiol can be converted to estrone *in vitro*, a process which is also known to occur *in vivo*. Estrone is very likely not the sole metabolite *in vitro* inasmuch as only about half of the estrogenic substance incubated could be recovered. This view is supported by earlier experiments (DeMeio *et al.*) wherein the biological inactivation of hormone was practically complete—the ratio of estradiol to liver tissue was 1 to 5,000 parts by weight.

Electrophoretic and chemical analyses of plasma and its fractions in health and disease H. ROWLAND PEARSON (by invitation) and ALICE CHANUTIN, *Biochemical Institute, Univ. of California, Berkeley, California*. Plasma is a complex

fractions obtained by *Method 6* of Cohn *et al* were analyzed for their electrophoretic distribution and protein nitrogen, total lipid carbon and cholesterol contents. Data are presented for normal individuals and for patients with diseases involving the kidneys, liver, and lungs. General trends are observed without the development of any characteristic pattern for these conditions. The plasma and fractions of multiple myeloma cases present specific electrophoretic patterns. The variations in the electrophoretic and chemical analyses are non-specific and do not yield sufficient information for diagnosis.

Comparative studies in niacin metabolism W A PERLZWEIG, FRED ROSEN (by invitation), I G LEDER (by invitation), S HUNTER (by invitation) and P B PEARSON *Dept of Biochemistry, Duke Univ, Durham, N C, and A and M College of Texas, College Station, Texas*. Data on the urinary excretion of the major known metabolites of niacin in various species after saturation with nicotinamide will be presented. In man approximately 90% of 7 mg/kg/day of nicotinamide was recovered in equal amounts of N¹-methyl-nicotinamide (NMN) and the 6-pyridone of NMN. The major end-product in the dog is NMN which accounts for 90% of 10–20 mg/kg/day. In the rat 50% of 100–200 mg/kg/day was recovered as NMN, 15% as free niacin, and only 3% as the 6-pyridone, leaving 30% unaccounted for. The excretion of NMN in the rabbit (100 mg/kg/day), guinea pig (200 mg/kg/day), goat (80 mg/kg/day), calf (50 mg/kg/day), sheep (50 mg/kg/day), and horse (25 mg/kg/day) is less than 1% of the dose. The rabbit and guinea pig excreted 3% as the 6-pyridone, whereas the goat, calf and sheep excreted less than 1% of this metabolite. After the ingestion of NMN approximately equal amounts of NMN and the 6-pyridone were found in the urine of man and the rabbit. However, in both species the sum of these metabolites accounts for only 50% of the dose. After ingestion of NMN, the rat excretes 50% unchanged and 3% 6-pyridone, leaving 47% unaccounted for. The recovery in the urine of a single oral dose of the 6-pyridone is approximately 70% (of 50 mg) in man, 85% (of 10 mg) in the rat, 90% (of 25 mg) in the rabbit and 40% (of 25 mg) in the guinea pig. These data establish the 6-pyridone as a major metabolite of excretion for man but not for the other species studied. The rabbit, guinea pig and the polygastric herbivora can metabolize large amounts of niacin to unknown end products.

Incorporation of radioactive amino acids into the protein of acellular liver homogenate fractions ELBERT A PETERSON (by invitation), THEODORE WINNICK, and DAVID M GREENBERG *Division of Biochemistry, Univ of California Medical School, Berkeley, Calif*. A homogenate is

employed which consists of equal parts of 1) cytoplasmic granules obtained by fractional centrifugation, and 2) supernatant from a concentrated (1) homogenate centrifuged at 2600 X g. Component (2) is completely inactive in the absence of (1). Component (1) serves as the locus for the amino acid incorporation process. However, radioactive protein appears in higher concentration in (2) during incubations with C¹⁴-labeled amino acids. Accordingly, the mixture of (1) and (2) gives best results. Component (1) is inactivated by freezing, (2) is not. 0.33 ml of the mixture, containing 0.020 gm protein, is incubated with either 0.4 μ M of labeled glycine or 0.8 μ M labeled DL-alanine at 37° in horizontally-rotated centrifuge tubes, flushed with oxygen. The incorporation process is stopped by the addition of trichloroacetic acid. The precipitated protein is centrifuged, washed repeatedly with trichloroacetic acid, and freed of lipid by extraction with hot alcohol-ether. The lipid contains bound radioactive serine, when labeled glycine is used in the incubations. After 1 hour, approximately 0.75 μ M of glycine or 0.35 μ M of alanine are incorporated per gm protein. These values represent uptakes of 3.8% of the glycine and 1.8% of the L-alanine employed in the experiments.

Some factors which influence the synthesis of peptide bonds as catalyzed by papain CORNELIUS W PETTINGA (by invitation) and SIDNEY W FOX *Chemical Laboratory, Iowa State College, Ames, Iowa*. The effects of various experimental conditions upon peptide bond synthesis as catalyzed by papain have been studied. The use of citrate buffer concentrations higher than had previously been reported, was especially effective in increasing the amount of benzoylamino acid anilide formed from the acid and aniline. The pH-yield curves for the reactions were similar in form for both 0.1M and 1.0M buffer concentrations with the optimum pH being near 5.0, pH-activity curves of similar shape have previously been obtained by others for other substrates. With the amounts of substrates, enzyme, and activator held constant, the yield of anilide decreased as the volume of buffer used was increased, for those acylamino acids studied. When benzoylamino acids of different solubility behavior were used, viz, benzoyl-DL-phenylalanine and benzoyl-DL-alanine, the effects of varied experimental conditions were nevertheless qualitatively similar. Six days' incubation gave only slightly greater yields than did 3 days' incubation, commercial papain catalyzed almost as well as a hydrogen sulfide-treated preparation, greater differences resulted when a more concentrated buffer was used, and from use of a higher ratio of aniline to benzoylamino acid. In the case of *N*-benzoyl-phenylalanine another important factor was the type of side-chain substitution. Related behavior

of substrates containing the same amino acid residues has been studied

Oxalacetate decarboxylase of *Azotobacter vinlandii* G W E PLATT (by invitation) and HENRY A LARDY Dept of Biochemistry, Univ of Wisconsin, Madison, Wis The enzyme oxalacetate decarboxylase was isolated from acetone dried cells of *Azotobacter vinlandii* by precipitation of inert proteins at pH 4.8, adsorption on copper hydroxide gel, elution with 0.1M pH 6.8 phosphate buffer and fractionation with ammonium sulfate. An increase in activity of 10-80 fold over that of the original aqueous extract of bacterial acetone powder was achieved. The purified decarboxylase was activated by Mn^{++} , Co^{++} , Zn^{++} and slightly by Mg^{++} . Pyrophosphate, ATP, and orthophosphate acted as inhibitors in the presence of Mn^{++} . When Co^{++} was the activator orthophosphate was not inhibitory. The inhibition by orthophosphate in the presence of Mn^{++} could be competitively reversed by Co^{++} indicating the existence of an inactive phosphate manganese enzyme complex. Co^{++} seems to compete with the phosphate manganese radicle for the same point of attachment on the enzyme. Malate inhibited when either Mn or Co^{++} were used as activators. No fixation of $C^{14}O_2$ into oxalacetate could be demonstrated in the presence of the purified enzyme. Neither was the incorporation of radioactive carbon dioxide stimulated by ATP, fumarate, orthophosphate, or pyruvate either singly or in combination. The lack of fixation indicates that this enzyme merely catalyzes the equilibrium reaction: oxalacetic acid \rightleftharpoons pyruvic acid + CO_2 ($K = 1.9 \times 10^3$) and is free of coupling enzyme systems. The biotin activities for *L. arabinosus* of enzyme fractions in various stages of purity were found to decrease with increasing purity.

Biosynthesis of carotenes in tomatoes JOHN W PORTER and RALPH E LINCOLN (introduced by F W QUACKENBUSH) Depts of Agricultural Chemistry and Botany and Plant Pathology, Purdue Univ, Lafayette, Ind. Several carotenes and 3 colorless polyenes have been found in small quantities in fruit of *Lycopersicon* species and strains. By breeding, it has been possible to obtain selections containing an increased content of 1 or more of these compounds. Chemical analysis of the more prominent colorless polyenes and carotenes has shown the structural similarity between these compounds and the well known carotenes. It is suggested that these compounds are intermediate steps in the synthesis of lycopene and *beta*-carotene. None of these compounds are found in quantities exceeding the quantity of lycopene in commercial tomatoes. Genetic studies have shown that a single gene difference exists between tomatoes containing lycopene and those yellow tomatoes containing little or no lycopene and only 2-3 μg of

carotene per gm of fruit. A single gene difference also exists between tomatoes containing lycopene and those containing predominantly *zeta* carotene and prolycopene. Another single gene difference exists between tomatoes containing lycopene and those containing *beta* carotene. From the chemical and genetic studies, it is postulated that the synthesis of carotenes in tomatoes proceeds from simple compounds through *zeta* carotene to lycopene and then to *beta* carotene. The chemical steps for the postulated scheme involve dehydrogenation to form lycopene, followed by ring formation to yield *beta* carotene. The scheme probably does not apply to carotene formation in green leaves.

Oxidative phosphorylation without deamination in mitochondrial preparations VAN R POTTER and W C SCHMIDT (by invitation) McArdle Memorial Laboratory, Medical School, Univ of Wisconsin, Madison, Wis. In isotonic homogenates phosphorylation could be coupled with the oxidation of mixtures of pyruvate and oxalacetate or fumarate via the Krebs cycle provided the reaction mixture was fortified with magnesium ions, inorganic phosphate and adenosine triphosphate (ATP) or muscle adenylic acid (AMP). During the period of active inorganic phosphate uptake, the rate of NH_3 liberation was very slow, but when the inorganic phosphate concentration began to rise following a decrease in either substrate or enzyme activity, the output of NH_3 began to accelerate and continued until the NH_3 formed was equal to the amount of ATP added. In these experiments the amount of whole homogenate per flask was low, usually 50 mg wet weight of tissue per flask. When homogenates in isotonic sucrose were fractionated by centrifugal means, the mitochondria from liver and kidney possessed considerably less than one-half of the oxidative activity of the whole homogenates, but if amounts of mitochondria were chosen so as to give an oxidative rate equivalent to what was obtained with the whole homogenate, the phosphate balance was maintained much longer with the mitochondria than with the whole homogenate and when phosphate output began, it was not followed by NH_3 output. The results conform with the view that ATP must be dephosphorylated before it can be deaminated. The presence of the deaminase appears to constitute an irreversible leak from the ATP-AMP system, and its separation from the mitochondria by centrifugal means facilitates the study of certain aspects of oxidative phosphorylation.

Water and electrolyte losses from skin of infants EDWARD L PRATT (by invitation), ROBERT E COOKE (by invitation) and DANIEL C DARROW Dept of Pediatrics, Yale Univ School of Medicine, New Haven, Conn. By balance techniques the water loss from the lungs and skin at 80°F was about 48 gm/kg of body weight per day. At 90°F it was

106 gm At 80° skin washings contained about 1 mm of chloride, 0.9 mm of sodium, and 1 mm of potassium per day At 90° skin washings contained about 5 mm of chloride, 4 mm of sodium, and 6 mm of potassium per day Calcium and phosphorus losses were negligible The concentrations of electrolyte in sweat were calculated using 2 assumptions First, all water losses from the skin at 90° were considered due to active sweating with no loss by diffusion Therefore, the volume of sweat equaled the total water loss from the lungs and skin at 90° minus $\frac{1}{3}$ of the insensible water loss at 80° The loss of water via the lungs was considered to be constant in the 2 periods and approximately equal to $\frac{1}{3}$ of the non-sweating insensible water loss Second, skin washings at 80° were considered to arise from desquamation The electrolyte in sweat equaled the skin washings at 90° minus the washings at 80° The concentrations per kg of sweat were about 5 mm of chloride, 4 mm of sodium, and 6 mm of potassium These data indicate a low concentration of sodium and chloride in the sweat of normal babies The concentration of potassium is high

Metabolism of acetone T D PRICE (by invitation) and D RITTENBERG *Dept of Biochemistry, College of Physicians and Surgeons, Columbia Univ, New York City* Acetone labeled with carbon-14 in the methyl groups was administered to rats From 0.2 to 1.1 mg of the acetone was given by stomach tube Little of the acetone is directly excreted, since only 0.6–10% of the acetone radioactivity was expired as carbonyl compounds However, 50–80% of the activity appears in the respiratory carbon dioxide within 24 hours The maximum activity in the expired carbon dioxide occurs about 2 hours after administration of the acetone, the activity of the carbon dioxide drops to a very low value after 12 hours The administration of phenylaminobutyric acid resulted in the urinary excretion of a radioactive acetyl derivative The activity of this product indicates that about half of the acetone was converted to acetate In the normal rat, significant activity appeared in the carbon of the following compounds arranged in order of decreasing specific activity: liver cholesterol, bone carbonate, carcass cholesterol, carcass glutamic acid, liver glycogen, carcass aspartic acid, total carcass amino acids, carcass arginine and carcass fatty acids No activity was found in the carcass leucine or tyrosine

Partial separation of D- and L-peptidases and analogous dehydropeptidase I VINCENT E PRICE (by invitation), ALTON MEISTER (by invitation) and JESSE P GREENSTEIN *National Cancer Institute, National Institutes of Health, Bethesda, Md* The enzymatic hydrolysis of glycyl-L-alanine, glycyl-D-alanine, and glycyldehydroalanine by aqueous homogenates of several normal rat tissues was studied By means of high speed centrifuga-

tion ($18,000 \times g$ for two hours) a partial separation of the enzymatic activities was achieved Between 75 and 95% of the original activity toward glycyl-D-alanine of homogenates of liver, kidney, spleen, brain, pancreas, testis and lung was associated with the sediment, whereas 80–95% of the original activity toward glycyl-L-alanine remained in the clear supernatant About 80% of the original activity toward glycyldehydroalanine was also found in the supernatant in all of the tissues examined except kidney, in which 80–90% of the activity was associated with the sediment Between 85 and 110% of the original activity was recovered in the pellet and supernatant fractions The ratio of D-peptidase, L-peptidase, and dehydropeptidase activities in a preparation derived from kidney sediment was 100:53:122, while the ratio for the original kidney homogenate was 100:193:105 A preparation obtained from lung sediment possessed these activities in a ratio of 100:31:22, compared to 100:230:60 for the original homogenate Thus in a variety of tissues D-peptidase activity may be readily separated from L-peptidase activity These results suggest that hydrolysis of the 3 substrates studied may be catalyzed by different enzymes The ratios obtained for the sediments support this hypothesis

Fate of mercury in the rat following administration as mercuric acetate and phenylmercuric acetate CLAUDIA S PRICKETT (by invitation), EDWIN P LAUG and FRIEDA KUNZE (by invitation) *Division of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D C* When phenylmercuric acetate and mercuric acetate are administered intravenously at a level of 120 μg Hg per rat, marked differences in the excretion and storage of mercury occur Thus, after mercuric acetate, 25% of the dose can be recovered in the kidney within 2 hours, only 4% after phenylmercuric acetate In the liver, the situation is reversed, with phenylmercuric acetate favoring greater storage In line with greater kidney storage after mercuric acetate is a significantly greater urinary excretion in 48 hours this amounts to 17% of the dose for mercuric acetate, but only 3% for phenylmercuric acetate The greater liver storage following phenylmercuric acetate is correlated with a prompt appearance of mercury in the small intestine, and a significantly elevated fecal excretion in 48 hours this amounted to nearly 40% for phenylmercuric acetate, and only 10% for mercuric acetate Oral administration, in contrast to intravenous results in much lower storage and excretion of mercury for both type of salts However, phenylmercuric acetate is absorbed to a much greater extent than mercuric acetate, approximately 5 times as much mercury being stored in the liver and kidney, and twice as much excreted in the urine

Identification of L-ascorbic acid in the urine

of normal and chlorotone-treated rats G W PROBST (by invitation) and M O SCHUITZ Division of Agricultural Biochemistry, Univ of Minnesota, Minneapolis, Minn Preliminary to other studies we have isolated and identified as L ascorbic acid (M P 191°, mixed M P 191°, $[\alpha]_D^{21}$ in methanol + 50.5, 174 mg equivalent to 1 mM iodine, monoacetone derivative M P 220°, 228 mg equivalent to 1 mM iodine) the indophenol reducing substance in urine of rats treated with 1,1,1-trichloro 2-methyl-2-propanol (Longenecker et al *J Biol Chem* 135 497, 1940) Rat urine oxidized with 2,6 dichlorophenolindophenol or norite and treated with 2,4-dinitrophenylhydrazine (DNPH) under conditions prescribed by Roe and Kuether (*J Biol Chem* 117 399, 1943) yields mixtures of DNPH-derivatives from which that of L-dehydroascorbic acid can be isolated in pure form by chromatography on magnesium phosphate tetrahydrate This derivative in 25 N H₂SO₄ has absorption maxima at λ 528 m μ ($E_{1\text{cm}}^{1\%}$ 415) and λ 370 m μ ($E_{1\text{cm}}^{1\%}$ 480) and a minimum at λ 448 m μ ($E_{1\text{cm}}^{1\%}$ 212) The extinction ratios $E_{1\text{cm}}^{1\%} \frac{\lambda 530}{\lambda 450}$ and $E_{1\text{cm}}^{1\%} \frac{\lambda 370}{\lambda 450}$ serve as an excellent criterion of its purity Depending upon the L ascorbic acid content of the urine, the oxidant and the conditions of incubation, compounds other than L-dehydroascorbic acid yield DNPH derivatives which when dissolved in 25 N H₂SO₄ and at λ 530 m μ account for 10-57% of the absorption of crude unchromatographed DNPH derivatives The implications of this to methodology for determination of L ascorbic acid will be discussed From urine of normal rats on a milk diet we have isolated the pure DNPH derivative of L-dehydroascorbic acid The latter, under suitable conditions, can be recovered quantitatively when L-ascorbic acid is added to urine

Studies on lysozyme CHARLES M PROCTOR and SHERMAN R DICKMAN (introduced by EMIL L SMITH) Dept of Biological Chemistry, Univ of Utah Medical School, Salt Lake City, Utah An assay for lysozyme consistent to 5% has been set up The increase in transmission at 4400 Å of *Sarcina lutea* suspensions is measured after incubation with the enzyme, followed by addition of alkali The effect of various agents on rate of lysis has been studied No inactivation resulted from treatment of lysozyme overnight at 22°C with 0.1 M alloxan or 2.0 M hydroxylamine, while 0.1 M sodium hydroxide resulted in about 50% inactivation Galston (1948, private communication) has observed an inactivation of several plant enzymes by incubation with riboflavin in strong light A 40% inactivation of lysozyme has been obtained under similar conditions Meyer and Hahnel (*J Biol Chem* 163

723, 1946) observed a striking increase in lysozyme activity by 0.2 M sodium chloride when estimated viscosimetrically, but no effect on the rate of appearance of reducing sugars This concentration of sodium chloride had no effect on the rate of lysis of *S. lutea*, whereas 0.5 M sodium chloride gave about 50% inhibition and 1.0 M sodium chloride 90% inhibition Treatment of either lysozyme or *S. lutea* cells with high concentrations of sodium chloride had no effect on subsequent lysis

Factors affecting the diazotization of bilirubin BETTY KING PROFFITT (by invitation) and DENNIS B MORRISON Dept of Chemistry, Univ of Tennessee, Memphis, Tenn The theory that serum bilirubin exists in more than one form is largely based on the difference in color developed when diazotization occurs in aqueous (direct reacting) and in alcoholic (total) solutions The difference in color resulting from indirect reacting bilirubin In an attempt to account for this difference we have investigated the diazotization of bilirubin over a wide range of conditions Crystalline bilirubin dissolved in buffers, diluted human bile, a protein-bilirubin complex isolated from human bladder bile, and sera from patients with different types of jaundice and varying degrees of hyperbilirubinemia was used The pH after diazotization of the above varied from 1-9 The concentration of nitrite in the diazo reagent was adjusted to optimum for any series and for a given pH From the data to be presented it will be evident that the concentration of nitrite is highly critical for aqueous solutions By adjustment of nitrite concentration it is possible to produce a biphasic reaction, maximum color and stability, fading colors or to suppress the development of color Methanol solutions are less sensitive since the methanol appears to destroy the excess nitrite Maximum color develops in aqueous solutions for all the materials tested at a pH 7-8 and optimum nitrite concentration All sera so far examined when diazotized with optimum nitrite concentration give a direct/total color ratio of approximately 0.7

Prothrombin consumption test ARMAND J QUICK AND JEAN FAVRE-GILLY (by invitation) Dept of Biochemistry, Marquette Univ School of Medicine, Milwaukee, Wis On adding serum to a mixture of CaCl₂, thromboplastin and fibrinogen, a coagulation time is obtained which can be employed as a measure of the prothrombin remaining unconverted during coagulation in a test tube The test has been standardized as follows As a source of fibrinogen, normal plasma is used which is treated with Ca₃(PO₄)₂ to adsorb prothrombin (component B) To a mixture of 0.1 cc of calcium phosphate-treated plasma, 0.1 cc of 0.02 M CaCl₂, and 0.1 cc of Quick's thromboplastin, 0.1 cc of serum is added and the time required to form a clot accurately measured The serum prothrombin

time (or prothrombin consumption time) for normal blood 1 hour after coagulation generally ranges from 16 to 35 seconds. In hemophilia it varies between 9 and 12 seconds and similar low values are found in severe thrombocytopenic purpura. The thrombin formed is inactivated so rapidly by the normal antithrombin that its effect on the test is not significant. Immediately after coagulation the serum prothrombin time is short (8-10 seconds) and remains constant for approximately 20 minutes or more before it begins to increase and finally reaches a maximum value. The increase in serum prothrombin time occurs sooner if the coagulated blood is centrifuged. The reason for this has not been determined.

Growth-promotion of yeasts by neopyrithiamin
JESSE C. RABINOWITZ (by invitation) and **ESMOND E. SNELL**, *Dept. of Biochemistry, College of Agriculture, Univ. of Wisconsin, Madison, Wis.* Several yeasts are inhibited by thiamin when grown in the absence of vitamin B₆ (Schultz and Atkin, *Arch. Biochem.* 14: 369, 1947). *Saccharomyces carlsbergensis* 4228, commonly used for determination of vitamin B₆, shows a similar behavior. In the absence of vitamin B₆ or thiamin, 3.0 mg. of dry cells were obtained per cc. of culture medium. The addition of only 0.017 mγ of thiamin per cc. of culture medium caused 50% growth inhibition, and the addition of 1.7 mγ of thiamin per cc. completely prevented growth. This inhibition of growth by thiamin is alleviated by either vitamin B₆ or by neopyrithiamin, a growth-inhibiting analogue of thiamin. Thus, in the absence of other data, neopyrithiamin might erroneously appear to act as an essential growth-factor for the yeast cells under these conditions. Inhibition of the organism by the addition of thiamin may result from increased synthesis of intermediate products, which may be toxic unless further metabolized. If vitamin B₆ were the limiting factor in this metabolic process, the addition of this vitamin would be expected to overcome the inhibition. Addition of neopyrithiamin would similarly overcome the inhibition since by acting as a competitive inhibitor of the added thiamin it could block formation of an excess of the toxic product. Thus, the antimetabolite would appear to be an essential growth factor, even though not involved in the normal metabolism of the cell. Reported instances in which organisms have come to require streptomycin or sulfonamides for growth may have a similar explanation.

Biosynthesis of heme **NORMAN S. RADIN** (by invitation), **D. RITTENBERG** and **DAVID SHEMIN**, *Dept. of Biochemistry, College of Physicians and Surgeons, Columbia Univ., New York City*. In an attempt to determine the precursors of heme we have incubated duck blood cells, both in plasma and buffer, with various compounds labeled with C¹⁴ and N¹⁵. The mixture of preformed and newly

synthesized heme was isolated as hemin and analyzed. Although the α-carbon and nitrogen atoms of glycine are utilized for porphyrin synthesis the carboxyl carbon atom is not. Comparison of C¹⁴ and N¹⁵ concentrations in hemin arising from glycine labeled in the α-carbon and nitrogen atoms suggests that more than 4 carbon atoms per heme molecule are derived from the α-carbon atom. The carboxyl carbon atom of acetic acid participates in the synthesis of heme. Degradation of this hemin reveals that about half of the activity is in the carboxyl group. Some of the activity is in the rings containing the vinyl side chains (rings I and II). The hemin obtained from methyl labeled acetic acid is 6 times as radioactive as that obtained from carboxyl labeled acetate. The α-carbon atom of pyruvic acid is also utilized. The implications of these findings in relation to the biosynthesis of porphyrins will be discussed.

Effect of Theiler's GD VII virus on P32 uptake of one-day-old-mouse brain cultures **MAX E. RAFELSON, JR.** (by invitation), **HAROLD E. PEARSON** (by invitation), and **RICHARD J. WINZLER**, *Depts. of Biochemistry and Bacteriology, Univ. of Southern California School of Medicine and Laboratory Division, Los Angeles County Hospital, Los Angeles, Calif.* The influence of Theiler's GD VII strain of mouse encephalomyelitis virus on the incorporation of P32-labelled phosphate into the phospholipid, total protein bound and organic acid-soluble fractions of minced one-day-old-mouse brain cultures incubated in Simm's solution at 35°C has been studied. The total protein bound phosphate was fractionated by combining the methods of Schmidt and Thannhauser (*J. Biol. Chem.* 161: 83, 1945) and Schneider (*J. Biol. Chem.* 161: 293, 1945) yielding four fractions: ribonucleic acid, deoxyribonucleic acid, phosphoprotein and inorganic phosphate liberated from phosphoprotein. The virus-infected cultures, in comparison with non-infected cultures, had a markedly higher rate of P32 incorporation into the phospholipid, total protein bound and ribonucleic acid fractions in the first 6-24 hours of incubation. This is the period of maximal virus propagation. Phosphate turnovers in the organic acid-soluble, phosphoprotein, deoxyribonucleic acid and protein-liberated inorganic phosphate fractions were no different in the infected than in noninfected cultures. Both infected and noninfected cultures had P32 uptakes increasing up to 48 hours of incubation after which time the relative specific activities of the fractions decreased.

A new ganglionic blocking agent **LOWELL O. RANDALL**, **WILLIAM G. PETERSON** (by invitation) and **G. LEHMANN**, *Pharmacology Dept., Hoffmann-La Roche, Inc., Nutley, N. J.* The d-3,4-(1',3'-Dibenzyl-2'-keto-imidazolido)-1,2-trimethylene-thiophanium d-camphor sulfonate (Nu-2222) is a

ganglionic blocking and vasodepressor agent which has about 30 times the potency and twice the duration of action of tetraethylammonium bromide. The vasodepressor effect is attributed to the blocking action on ganglia. Nu-2222 blocks transmission through the superior cervical ganglia since the reaction of the nictitating membrane to preganglionic stimulation is inhibited while the response to postganglionic stimulation is not affected. It blocks the vasodepressor response to vagus stimulation and the vasopressor response to carotid occlusion. The vasodepressor and ganglionic effects are counteracted by large doses of acetylcholine and Prostigmin. Ephedrine is an effective antidote for the vasodepressor action. Relatively large doses inhibit gastric and intestinal motility. There is little or no demonstrable curare-like action. Nu-2222 is 2 to 4 times as toxic as tetraethylammonium bromide by the intravenous route in mice, rats and rabbits but about 75 times as toxic in dogs. Lethal doses produce a hemorrhagic disorder in dogs which is accompanied by a prolonged clotting time. Such effects are not apparent in rabbits or cats. Nu-2222 has an approximate safety margin of 25 in dogs and 700 in rabbits.

Enzymatic mechanism of arginine synthesis
S. RATNER and ANNE PAPPAS (by invitation)
Dept. of Pharmacology, New York Univ. College of Medicine, New York City. It has been reported previously (S. Ratner, *J. Biol. Chem.* 170: 760, 1947) that rapid synthesis of arginine from citrulline occurs with partially purified enzyme preparations from extracts of beef liver acetone powder. The isolated system catalyzes the overall reaction: $L\text{-citrulline} + L\text{-aspartate} + \text{adenosinetriphosphate (ATP)} \rightarrow L\text{-arginine} + L\text{-malate} + \text{ADP} + \text{H}_2\text{PO}_4$. The reaction has been found to proceed in several steps. Two distinct enzymes have now been obtained by fractionation with ammonium sulfate. One of these catalyzes a reaction between citrulline and aspartic acid to form an intermediate condensation product. ATP participates in the condensation reaction and inorganic phosphate is formed as citrulline is removed. A portion of the endergonic requirement of urea synthesis may therefore be associated with the formation of this condensation product, the necessary energy being derived from the high energy phosphate group of ATP. Magnesium ion is required and 0.01 M fluoride causes a 60% inhibition. The second enzyme catalyzes the hydrolytic cleavage of the intermediate accumulated in the first step, with the simultaneous appearance of arginine and malic acid. Experimental details relating to the enzymatic mechanisms and to the fractionation procedure will be discussed. Experiments on homogenates demonstrate that the above mechanism represents the main pathway of the conversion of citrulline to arginine in the biosynthesis of urea.

Studies on prolamines treated with nitrogen trichloride I Fractionation of hydrolysates
L. REINER, PHILIP WEISS (by invitation), FERNANDA MISANI (by invitation), M. G. CORDASCO (by invitation), and T. W. FAIR (by invitation) *Research Laboratories, Wallace & Tiernan Products, Inc., Belleville, N. J.* Finely divided zein and gliadin were reacted with NCl_3 vapors or by suspending them in a solution of NCl_3 in carbon tetrachloride. About 20 gm. of NCl_3 are used up per kg. of prolamine. The reacted prolamine produces typical running fits in rabbits in a minimum dose corresponding to 500 mg. N orally. Zein was hydrolyzed with pancreatin and with Protease 16 to an $-\text{NH}_2/\text{N}$ value (formol titration) of 45-65% without impairment of its toxicity. It was then adsorbed to a cation exchange resin from which it was eluted with 2% pyridine. The eluate was toxic in a dose of 220 mg. N/kg. in rabbits, orally. Repeating this procedure with the first eluate yielded a second eluate which was toxic in a dose of 70 mg. N/kg. The second eluate was passed through charcoal previously conditioned with dilute acetic acid. The adsorbed material was eluted with large volumes of water. The combined eluate was toxic at a dose of 20 mg. N/kg. and some fractions of the eluate were toxic at a dose of 10 mg. N/kg. Part of the dried residue of the eluate was crystallized from EtOH. This was also toxic at 10 mg. N/kg. Its paper chromatogram (butanol-acetic acid) contained 5 spots suggesting that the product was not pure.

Studies on prolamines treated with nitrogen trichloride II Acetylated zein
L. REINER, FERNANDA MISANI (by invitation), PHILIP WEISS (by invitation), M. G. CORDASCO (by invitation), and T. W. FAIR (by invitation) *Research Laboratories, Wallace & Tiernan Products, Inc., Belleville, N. J.* Fractions which were isolated from zein treated with NCl_3 and which were toxic to rabbits in a dose corresponding to 36-220 mg. N/kg. were acetylated with acetic anhydride. The acetylated products did not produce running fits in dogs or rabbits when fed in doses 4 times as great as the minimum toxic dose of the unacetylated parent compound. Hydrolysis with 5N HCl reestablished their toxicity. Differences in the ability to acetylate *in vivo* may account for the great differences in the sensitivity of various species towards NCl_3 treated prolamines. Unhydrolyzed toxic zein was also detoxified by acetylation. Toxic zein lost its ability to produce fits when it was deaminated by diazotization. When zein was first acetylated, then treated with NCl_3 , a product resulted which was as a rule less toxic, but it became more toxic upon deacetylation. These results suggest that a free $-\text{NH}_2$ group which is at the end of a peptide chain is essential for the elicitation of the toxicity but that blocking this group by acetylation does not interfere with the

formation of the toxic residue through reaction with NCl_2 .

Determination of serum protein Studies of agents for separation of albumin and globulin JOHN G REINHOLD, L W BLUEMLE, JR (by invitation), FRANCISCO CAMPOY (by invitation), LOGAN GILMAN (by invitation), EDWARD F GOULD (by invitation), VERNON L MARTENS (by invitation) and RICHARD SHUMAN (by invitation) *Pepper Laboratory of Clinical Medicine and Nutritional Service, Hospital of the Univ of Pennsylvania, Philadelphia, Penna* Need exists for a rapid procedure for determination of serum albumin and globulin incorporating advances made recently in this field. A survey of agents proposed for separation of serum albumin and globulin was made by comparing the results with those of electrophoretic measurements at pH 8.6 and ionic strength 0.1. Sodium sulfate at a concentration of 26% and an approximate pH of 7.0 gave results approximating albumin and globulin values found by electrophoresis. Values obtained by use of sodium sulfite at 26.9% concentration were in fair agreement, while results obtained using 0.5 saturated ammonium sulfate (at a pH of 5.4 or 7.0), or methanol at 42.5% concentration pH of 6.8 and temperature of 1°C were less satisfactory. None of the salting-out methods were consistently in agreement with the electrophoretic separations. Attention to details of technique in the salting-out procedures appears important. The rapid separation method employing ether and centrifugation devised by Kingsley gave results similar to those obtained by filtration when 26% sodium sulfate was used. The applicability of the biuret reaction has been reevaluated. Determinations made by the biuret methods of Kingsley or Weichselbaum were compared with those of Kjeldahl or gravimetric methods. The means of all methods agreed closely, but occasional individual variations were marked. Discrepancies were least frequent between Kjeldahl and Weichselbaum biuret methods and the two may be used interchangeably for the usual serum analyses.

Influence of high levels of fat with suboptimal levels of riboflavin on the growth of chicks RAYMOND REISER (by invitation) and P B PEARSON *Agricultural and Mechanical College of Texas, College Station, Tex* Chicks receiving moderately high levels of refined cottonseed oil (Wesson Oil) in diets low in biotin ceased to grow much sooner than those on a similar diet without added fat. The higher the cottonseed oil content of the diet the greater the inhibitory effect on the rate of gain. The addition of riboflavin to the diets at a level of 4 $\mu\text{g}/\text{gm}$ of feed prevented or corrected the phenomenon. Lard did not retard the growth rate on low riboflavin diets and a commercial hydrogenated vegetable oil to only a slight degree. The effect is not due to the development of rancidity in the high fat diets. The efficiency of utilization of the

feed was lower on the cottonseed oil diets than on the low fat diets at low levels of riboflavin, but no differences were found in the riboflavin content of the livers.

Liver respiration as related to its xanthine oxidase activity DAN A. RICHERT (by invitation) and W W WESTERFELD *Dept of Biochemistry, Syracuse Univ College of Medicine, Syracuse, N Y* The determination of xanthine oxidase activity (Axelrod and Elvehjem) in a series of rat livers whose xanthine oxidase activity varied from 0-1800 units ($\text{Cmm O}_2/\text{gm}/\text{dry liver}/\text{hour}$) has demonstrated the following: 1) The initial rate of the endogenous respiration of liver decreased 50% as the xanthine oxidase activity fell from 1600 units to zero. 2) Tipping in xanthine to a respiring liver brei of low xanthine oxidase activity inhibited the endogenous respiration instead of increasing the oxygen consumption. 3) Adding hypoxanthine to the brei at the start intensified the xanthine inhibition effect and prevented the detection of xanthine oxidase in livers with normal activity. 4) Adding purified milk xanthine oxidase to livers of low activity restored the endogenous respiration to normal and prevented the inhibition otherwise caused by tipping in xanthine. 5) Dialysis of the liver brei removed the substrates otherwise detected by adding purified xanthine oxidase, and also removed the xanthine inhibition effect. The results show that about 50% of the initial endogenous respiration in a normal rat liver homogenate is due to the oxidation of one or more substrates similar to hypoxanthine, and the relative accumulation of such substrates in a brei with low xanthine oxidase activity is responsible for the inhibition produced by added xanthine, in accordance with the known enzyme-substrate relationships for this system.

Utilization of human serum albumin injected intravenously CECILIA RIEGEL and NICHOLAS GIMBEL (by invitation) *Harrison Dept of Surgical Research, Schools of Medicine, Univ of Pennsylvania, Philadelphia, Penna* Human serum albumin was administered both orally and intravenously as the sole source of protein to 3 human volunteer subjects. Control periods using either milk or casein orally were also studied. Nitrogen, calcium, potassium, phosphorus and sulfur balances, changes in albumin-globulin ratio in the blood, blood and plasma volumes, thiocyanate space, nitrogen content of leg lymph and urea excretion were determined. Albumin administered orally was utilized in comparable fashion to milk and casein. On an oral intake of albumin of 12.0 gm nitrogen daily 1 of 2 subjects was in nitrogen equilibrium, 1 had a daily negative balance of 1.6 gm. A 3rd subject was in negative balance on an oral intake of 8.0 gm nitrogen daily. All 3 were in marked positive balance on an intravenous intake of either 8.0 or 12.0 gm of albumin nitrogen daily.

From 1) increase in total circulating plasma protein, 2) excess circulating interstitial fluid albumin, as determined from thiocyanate space determinations and from analysis of lymph obtained from the leg, and 3) amount of albumin excreted in the urine as albumin, we can, in *Patient S*, account for 774 of the 1100 gm injected over a period of 22 days, leaving 326 gm to be accounted for. If the difference between an assumed endogenous nitrogen excretion and the actually determined nitrogen excretion represents metabolic breakdown of albumin, the excretion of this amount of nitrogen in the urine is more than sufficient to account for the injected albumin not present in the body fluids. It is possible that this amount of albumin may have been metabolized during the 22 days of injection. That such breakdown is slow is indicated by the steady accumulation of albumin in plasma the longer the albumin injections were continued, by the low level of nitrogen excretion during the period when albumin was administered intravenously, and by a slowly increasing excretion of sulfur, which fell to a very low level when the subject was first changed from oral albumin to intravenous albumin.

Studies on the origin of serum proteins SIDNEY ROBERTS (by invitation) and ABRAHAM WHITE, *Dept of Physiological Chemistry, School of Medicine, Univ of California at Los Angeles, Los Angeles, Calif*. Serum protein levels have been determined electrophoretically in the rat after either partial hepatectomy or abdominal evisceration. After partial hepatectomy, the earliest change was a decline in α_1 -globulin, followed by later decreases in albumin and in the other globulins. Subsequently, the globulins, especially α_1 -globulin, were rapidly restored. Albumin levels, however, remained low over the 48 hour experimental period. A maximum reduction in total serum protein concentration of 1.2 gm/100 ml occurred 24 hours after partial hepatectomy. Following abdominal evisceration, the serum protein level dropped rapidly, falling 2.0 gm/100 ml within the 23-hour experimental period. In this instance, the decline was due almost entirely to a diminution of albumin. Incubation of surviving liver mince in rat serum in an atmosphere of 95% oxygen, 5% carbon dioxide resulted in the liberation of large amounts of a protein with the electric mobility of serum

α globulin. The rate of liberation of this liver protein was initially as high as 30 mg/gm of tissue per hour, but declined rapidly over the 3 hour incubation period. Similar experiments in a nitrogen atmosphere resulted in an increased rate of liberation of protein. In all experiments, a disappearance of albumin from the serum medium accompanied the release of ' α globulin'. The results provide further evidence that the formation of blood proteins involves the integrated action of the liver and extra-hepatic tissues.

Tissue collagen in experimental scurvy WILLIAM V B ROBERTSON (introduced by H B PIERCE), *Division of Experimental Medicine and Dept of Biochemistry, College of Medicine, Univ of Vermont, Burlington, Vt*. The collagen concentrations in the skin and liver of normal guinea pigs, of those on a scorbutogenic diet and moribund with acute scurvy, and those on a scorbutogenic diet but maintained deficient for about 10 weeks with 0.35-0.15 mg of ascorbic acid per day were determined. No changes in the collagen concentration in skin were found, whereas that in the liver was higher than normal in both scorbutic groups. The implications of these findings will be discussed.

Chemical changes in isotonic saline solutions placed in successively lower levels of human small intestine C S ROBINSON, GLADYS R BUCHER (by invitation) and D DZIEWIATKOWSKI (by invitation), *Dept of Biochemistry, Vanderbilt Univ, Nashville, Tenn*. The survey of the gradient in the small intestine altering saline solutions introduced at successive levels spaced 60 minutes apart, through a Miller-Abbott tube, has been continued using 50 cc volumes per instillation of approximately isotonic solutions of Na_2SO_4 , NaH_2PO_4 or Na_2HPO_4 . Samples withdrawn 20 minutes after instillations were analyzed for total base, total CO_2 , pH and the anions. The differences between successive pairs of samples (lower minus upper) were examined statistically. The average differences, with standard error, which represent the rate of change at intestinal levels 60 minutes apart as the tube advanced from pylorus to terminal ileum, are tabulated. A = number of samples, B = number of subjects, C = hours pylorus-terminal ileum, D = volume recovered in 60 minutes, E = mean difference in pH.

Saline used	A	B	C	D	E
NaCl , 50 cc 150 mM	88	14	7-8	52.5 \pm 3 cc	+0.186 \pm 0.03*
Na_2SO_4 , 50 cc 112 mM	28	8	4-5	63.7 \pm 3 cc*	+0.290 \pm 0.05*
NaH_2PO_4 , 50 cc 104 mM	48	11	6-7	74.4 \pm 3 cc*	+0.036 \pm 0.02
Na_2HPO_4 , 50 cc 101-143 mM	52	11	5-6	62.3 \pm 4 cc*	+0.109 \pm 0.02*
Total Base	mm CO_2		Cl mEq/l		SO_4 mEq/l PO_4 mEq/l
NaCl , +0.70 \pm 0.28*	+3.80 \pm 0.63*		-3.32 \pm 0.80*		+9.57 \pm 4.8*
Na_2SO_4 , +1.02 \pm 0.11	+4.54 \pm 1.09*		-7.1 \pm 2.99*		+9.3 \pm 6.9
NaH_2PO_4 , +0.67 \pm 0.17	+0.82 \pm 0.24*		-9.9 \pm 2.80*		+9.6 \pm 6.2
Na_2HPO_4 , +4.80 \pm 0.13*	+0.97 \pm 0.40*		-5.6 \pm 2.24*		

The differences marked * are statistically significant. Sulfate and phosphate ions suppress the entrance of chloride and this suppression is more pronounced as the ileocecal valve is approached.

Analysis of certain components of skeletal muscle during vitamin E deficiency CHARLOTTE E RODERUCK (introduced by H A MATTILL) *Dept of Biochemistry, State Univ of Iowa, Iowa City, Iowa* In nutritional muscular dystrophy resulting from a deficiency of vitamin E, the free and total biotin content of skeletal muscle of hamsters, rabbits and guinea pigs did not vary from that of control animals. Reduction of the biotin intake (hamsters) decreased muscle biotin irrespective of the adequacy of the vitamin E intake. It is therefore unlikely that vitamin E acts as an antioxidant in tissue to preserve biotin, although this relationship has been observed in the autooxidative destruction of biotin by unsaturated fats *in vitro*. A sparing action of vitamin E on DPN was not demonstrated by mere addition of coenzyme I to Ringer phosphate medium in which dystrophic muscle strips were respiring, Q_{O_2} was not affected. Q_{O_2} values were also not influenced by addition of glucose, glutamic acid or phenylalanine. Muscle strips from hamsters on vitamin E-deficient diets but not grossly dystrophic had Q_{O_2} values 33% higher than those from control animals. Differences of the same order were found in control and dystrophic guinea pig muscle. The glutamine content of skeletal muscles of dystrophic guinea pigs was about one-third that of muscle from control animals, the average content of non-glutamine amino acids was unchanged. In vitamin E deficient rabbits, the difference was less marked. The possible significance of decreased glutamine levels is discussed briefly with reference to energy relationships. These results may be further evidence of an inefficient expenditure of energy possibly due to impairment in the process of phosphorylation.

Effect of a series of flavanoids on hyaluronidase activity GERTRUDE RODNEY, L M WHEELER and ANN SWANSON (introduced by J J Pfiffner) *Research Laboratories, Parke, Davis & Co, Detroit, Mich.* The action of a series of flavanoids related to rutin on bovine hyaluronidase was studied *in vitro* by both the viscosity-reduction test and the turbidity-reduction method. Crystalline rutin was found to have no effect in concentrations of $5 \times 10^{-4}M$ to $1 \times 10^{-3}M$ on 10 units of enzyme but a product formed by pancreatic digestions showed some inhibition of the enzyme activity. Investigation of a series of 15 related flavanoids showed inhibitory activities which could be correlated with structural differences in the compounds. The action of these compounds *in vivo* on the spreading effect of hyaluronidase injected with hemoglobin in guinea pig skin was compared to the activity shown *in vitro*.

Studies in the metabolism of d-arabinose JOSEPH H ROE, EUGENE W RICE (by invitation) and BENJAMIN W SMITH (by invitation) *Dept of Biochemistry, School of Medicine, George Washing-*

ton Univ, Washington, D C Following oral administration of D-Arabinose to rabbits, in doses of 2 gm/kg of body weight, this sugar appears in the blood within $\frac{1}{2}$ hour, reaches a peak level in 1-2 hours and disappears from the blood stream in 6-8 hours. The rate of absorption of D-Arabinose in the rabbit, determined by the Cori technique, was found to be 0.036 gm/100 gms of body weight/hour. Balance studies after the oral administration of D-Arabinose, in which analyses of the alimentary tract, tissues, feces and urine were made, showed the following average total recoveries of this sugar: after 1 hour, 80%, after 2 hours, 67%, after 6 hours, 15%, after 12 hours, 9.5%, after 24 hours, 5.9%. In the 24-hour analyses the pentose was found only in the urine. Analyses were made with the colorimetric method of Roe and Rice (*J Biol Chem* 183: 507, 1948) which is based on furfural formation. These data show that D-Arabinose undergoes a metabolic transformation in the rabbit. *In vitro* studies of D-Arabinose added to homogenates of liver, kidney, muscle, blood and brain have shown a disappearance of this sugar after 13 to 24 hours' incubation at 37°C, under aerobic and anaerobic conditions. This disappearance is prevented by heating, iodoacetic acid and fluoride.

Hemolytic action of alloxan and alloxan derivatives CATHARINE S ROSE (by invitation) and PAUL GIBRGY *Nutritional Service of the Dept of Pediatrics and the Gastro-Intestinal Section of the Medical Clinic, School of Medicine, Univ of Pennsylvania, Philadelphia, Penna.* In the course of studies on the effect of dietary factors in alloxan diabetes it was found that alloxan caused marked hemolysis in rats receiving a tocopherol-deficient diet (*Science* 108: 716, 1948). The nature of this reaction has been investigated. Dialuric acid, alloxantin and ninhydrin caused hemolysis in the same manner as alloxan, ninhydrin being the most active of the substances tested. The increased fragility of the red blood cells towards these compounds could be demonstrated after the rats had received the tocopherol-deficient diet for only 1 week. Alloxanic acid did not cause hemolysis. Studies were made *in vitro* using a suspension of red blood cells, all substances tested for hemolytic activity were prepared in phosphate buffer at pH 7.4. With dialuric acid the cells of tocopherol deficient animals were hemolyzed. Alloxan was without effect, but treated with an equivalent amount of cysteine it behaved as dialuric acid. Larger amounts of cysteine inhibited hemolysis with either alloxan or dialuric acid. Various alloxan-related compounds and reducing agents have been studied. The red blood cells of animals receiving tocopherol were resistant to the action of dialuric acid and addition of tocopherol in about 1/50th the amount of dialuric acid protected the cells of tocopherol-deficient animals. These observations are in accord with an as

sumption that tocopherol intereferes with the formation of a free radical, a first oxidation product of dialuric acid, which is the actual hemolytic agent.

In vitro action of gentisic acid on hyaluronidase
SAUL ROSEMAN (by invitation), FAITH PEARSON (by invitation), and ALBERT DORFMAN *Dept of Pediatrics, Univ of Chicago, Chicago, Ill* The administration of sodium salicylate to rabbits inhibits the spreading effect of hyaluronidase (Guerra, F, *J Pharmacol & Exper Therap* 87: 193, 1946) It has been demonstrated that salicylates do not inhibit hyaluronidase *in vitro* in concentrations that are achieved *in vivo* (Dorfman, Reimers, and Ott *Proc Soc Exper Biol & Med*, 64: 357, 1947, Pike *Science*, 105: 391, 1947, Meyer *Physiol Rev* 27: 337, 1947) Meyer and Ragin (*Science* 108: 281, 1948) have recently claimed that this is due to the fact that salicylates are converted to gentisic acid which acts as the true inhibitor Analytically pure gentisic acid was prepared by the oxidation of salicylic acid Purification was achieved through lead salt fractionation and repeated recrystallization from water and ethyl acetate Gentisic acid so prepared did not inhibit bovine testicular hyaluronidase This confirms the findings of Lowenthal and Gagnon (*Canad J Research* 26: 200, 1948) Crude fractions were found to be inhibitory as was pure gentisic acid treated with alkali in the presence of air Similar results were obtained with homogentisic acid Thus the apparent inhibitory effect of crude gentisic acid is due to impurity which is probably an oxidation product The possible significance of these results in the explanation of the *in vivo* effects of salicylates will be discussed

Arginase, rhodanese ATPase activity of regenerating livers in protein-depleted rats
OTTO ROSENTHAL, CHARLES S ROGERS (by invitation) and COLIN C FERGUSON (by invitation) *Harrison Dept of Surgical Research, Schools of Medicine, Univ of Pennsylvania, Philadelphia, Penna* Arginase, rhodanese and ATPase activities of regenerating liver following 70% hepatectomy have been studied in male 250-gm Wistar rats maintained on a protein-free diet Enzyme assays and determinations of the protein nitrogen were done upon aliquots of glass-homogenized tissue specimens During 2 weeks of preoperative protein starvation the animals lost about 44% of the protein, 70% of the arginase, 65% of the rhodanese, and 50% of the ATPase of their livers Thus while arginase and rhodanese activities of the liver protein were markedly diminished ATPase activity decreased but little Following partial hepatectomy the concentrations of rhodanese and ATPase in the regenerating remnant continued to decrease slightly whereas the arginase concentration rose strikingly The rise was apparent as early as 12 hours after hepatectomy At 24 to 48 hours, i e, at a time when

only about 36% of the operatively removed protein was regenerated, the liver remnant contained as much or even more arginase than the entire pre-operative liver Smaller changes in arginase were found in livers examined 4 to 8 days after partial hepatectomy The fluctuations of the liver arginase concentrations are probably a reflection of the changes in the endogenous protein metabolism which temporarily increases as a consequence of traumatic tissue breakdown and inadequate food consumption No similar changes were observed in regenerating livers of rats kept on an 18% casein diet during the entire experimental period

Hydrolysis of esters by rabbit polymorphonuclear leucocytes
R J ROSSITER and ESTHER WONG (by invitation) *Dept of Biochemistry, Univ of Western Ontario, London, Canada* It has been found that washed suspensions of rabbit polymorphonuclear leucocytes, besides hydrolysing phosphate esters (*Biochem J* 43: 111, 1948), also hydrolysed simple methyl esters of the aliphatic acids That polymorphonuclear leucocytes hydrolyse tributyrin has been reported previously by Fleischmann (*Biochem Ztschr* 200: 25, 1928) and by Barnes (*Brit J Exper Path* 21: 264, 1940) These workers, however, referred to the enzyme as a lipase It has now been shown that the enzyme is capable of hydrolysing simple triglycerides and simple methyl esters (up to C_8 have been tested), but not higher glycerides such as triolein The enzyme should, therefore, be referred to as an esterase rather than a lipase The rabbit polymorphonuclear leucocyte can hydrolyse neither acetylcholine, acetyl- β -methylcholine nor benzoylcholine and, therefore, contains neither 'true' cholinesterase, 'pseudo'-cholinesterase nor specific benzoylcholinesterase

Studies on copper-containing oxidases in higher plants
M L ROTHCHILD and ROBERT MACVICAR (introduced by V G HELLER) *Depts of Chemistry, Oklahoma A and M College and Agricultural Chemistry Research, Oklahoma Agricultural Experiment Station, Stillwater, Okla* The distribution of polyphenol oxidase and ascorbic acid oxidase in leaf-blade tissue of several species of higher plants has been determined Rapid oxidation of both catechol and 3,4-dihydroxy-DL-phenylalanine occurred in the presence of leaf tissue homogenates of several species of *Dicotyledonaceae* Of the plants studied tomato and sweet potato contained the most highly active enzyme system Polyphenoloxidase activity could not be demonstrated in wheat leaf-blade homogenate Ascorbic acid oxidase was present in sweet potato, soybean, and tomato leaf tissue, Swiss chard and wheat were less active Sodium diethyldithiocarbamate in concentration of 0.01 and 0.01M did not appreciably inhibit O_2 consumption by leaf tissue homogenates in the presence of added DOPA, ascorbic acid oxidation was

markedly inhibited by both concentrations of this substance. The endogenous rate of O_2 consumption was not significantly affected by this inhibitor. Copper deficient tomato plants showed a marked decrease in polyphenoloxidase and ascorbic acid oxidase activity. The administration of copper ions resulted in rapid restoration of oxidative activity of these two enzyme systems.

Relationship of cell surface phosphatases to sugar metabolism in yeast. ASER ROTHSTEIN and REBECCA MEIER (introduced by H. C. HODGE). *Atomic Energy Project of the Univ. of Rochester, Rochester, N. Y.* It has been shown that the surface of the yeast cell contains phosphatases, which can dephosphorylate a large variety of compounds including phosphorylated sugars. The surface phosphatases can be completely inhibited by very low concentrations of molybdate or tungstate without any apparent injury to the cell. The inhibition is reversible and competitive in nature. It seems to be specific for the phosphatases. In the absence of molybdate, phosphorylated sugars can be metabolized at a slow rate which is limited by the rate of dephosphorylation. In the presence of molybdate, the phosphorylated sugars are not metabolized at all although glucose and fructose are consumed at a normal rate. It can be concluded, therefore, that phosphorylated sugars cannot be metabolized directly as such, but that the sugar residue can be metabolized after the phosphate group is split off. The function of the cell-surface phosphatases seems to be limited to the splitting of phosphate containing compound in the medium into utilizable residues, with no direct role in carbohydrate metabolism involved.

Inhibition of oxidation and phosphorylation in kidney homogenates by yeast adenylic acid. HENRY Z. SABLE (introduced by CARL F. CORI). *Dept. of Biological Chemistry, Washington Univ. School of Medicine, St. Louis, Mo.* Various agents are known to inhibit aerobic phosphorylation in tissue homogenates. It was found that the oxygen consumption of washed kidney particles was increased to a maximum value, when, in addition to glutamate, Mg^{++} and fluoride, about $1 \mu M$ of muscle adenylic acid (adenosine 5' phosphoric acid) was added per 2 ml of reaction mixture. Increasing amounts of this nucleotide up to $12 \mu M$ caused a progressive increase in the uptake of inorganic phosphate from the medium, and correspondingly increased formation of acid labile phosphate compounds. When $6 \mu M$ of yeast adenylic acid (adenosine-3'-phosphoric acid) was added along with $12 \mu M$ of muscle adenylic acid, oxygen consumption was decreased, in a particular experiment, from 34 to $10 \mu M$, uptake of inorganic phosphate was decreased from 775 to $107 \mu g$ and formation of acid labile phosphate was decreased from 553 to $130 \mu g$. In a similar experiment muscle inosinic acid

(inosine-5'-phosphoric acid) in place of yeast adenylic acid had no inhibitory effect. The inhibitory effect of yeast adenylic acid on phosphorylation is probably due to competition with muscle adenylic acid for the enzyme which catalyzes the transfer of phosphate from intermediates formed during oxidation.

Formation of serine from glycine in the intact rat. WARWICK SAKAMI (introduced by HARLAND G. WOOD). *Dept. of Biochemistry, Western Reserve Univ. School of Medicine, Cleveland, Ohio.* Glycine has been shown to condense with formate or a formate derivative to form serine. When C^{13} carboxyl-labeled glycine and C^{14} -labeled formate were administered to rats the liver serine was found to contain the C^{13} in the carboxy group and C^{14} largely in the β -position. In the present investigation we have studied the physiological formation of 'formate'. A possible mechanism is the deamination of glycine (Ratner, Nozito and Green) and oxidative decarboxylation of the resulting glyoxylic acid: glycine \rightarrow glyoxylic acid \rightarrow 'formate' + CO_2 . To test the possible significance of this pathway in providing 'formate' for the conversion of glycine to serine we have administered glycine labeled with C^{14} in the methyl carbon to rats by stomach tube and determined the distribution of isotope in the liver serine and glycogen. The β -carbon of serine was almost (80%) as active as the α -carbon while the C^{14} was equally distributed between the 1, 6 and 2, 5 carbons of the glucose units of the glycogen. These results indicate that glycine itself may provide the formate or formate derivative involved in its conversion to serine. The data of Winnick, Moring-Claesson and Greenberg are in accord with this view. The β -carbon of their serine isolated from liver homogenate after equilibration with C^{14} methyl-labeled glycine contained a small amount of the isotope.

Tryptophane requirement of the rat as related to dietary level of other amino acids. W. D. SALMON. *Laboratory of Animal Nutrition, Alabama Polytechnic Institute, Auburn, Ala.* The addition of 12% of acid hydrolysate of casein or an equivalent amount of gelatine to basal diets containing 7% of casein, 0.02% of niacin, and either 40% of corn grits or 7% of corn gluten meal depressed growth of rats. The growth depression was corrected by DL-tryptophane but not by additional niacin, 0.5% of DL-tryptophane added to the diet prevented growth depression or even supported growth at a higher rate than was obtained on the original basal diet. When the casein content of the basal diet was increased to 20%, the addition of gelatine depressed growth only if niacin was omitted from the diet. With niacin in the diet, this level of casein provided sufficient surplus tryptophane to balance the added gelatine. When 5% of glycine was added to the diets containing 7% of casein, growth was de-

Pressed and the effect was not nullified by either niacin or tryptophane, the further addition of casein hydrolysate restored growth. Moreover, 5% of glycine added to a 21% casein basal diet, containing adequate niacin, did not depress growth significantly. It is apparent that, as the dietary level of other amino acids is increased, the essential requirement for tryptophane is also increased. The results with glycine suggest that the requirement for other essential amino acids may be similarly increased.

Effect of x-ray radiation and of starvation on hemoglobin synthesis in the rat. K. SALOMON, K. I. ALTMAN, G. W. CASARETT, and T. R. NOONAN (introduced by F. L. HAVEN). *Dept. of Radiation Biology, Univ. of Rochester School of Medicine and Dentistry, Rochester, N. Y.* After whole body radiation and in acute starvation erythropoiesis is depressed. Information concerning the anabolism of the circulating hemoglobin under these conditions seems desirable. Since the alpha-carbon atom of glycine has been shown to be incorporated in hemin and globin, methylene labeled glycine was used in this investigation. Glycine (one or two microcuries) was administered to radiated and to starved rats. All animals were killed 24 hours later. Hemoglobin, hemin and globin were isolated from their blood and the C^{14} content of these compounds determined. The C^{14} activity ratio of hemin to globin on a gram to gram basis was found to range from 4-13 in all control animals. The ratio of C^{14} activity of hemin to globin isolated from rats injected with glycine immediately after radiation with 600 r varied from 25 to 32. Hemin synthesis was increased in all these rats. On the other hand, when glycine was injected six days after exposure to 600 r no measurable hemin synthesis occurred, and the activity ratio was found to be zero. The activity ratio after five days starvation was 64, hemin synthesis in these rats was increased whereas globin formation was depressed. In seven days starvation the activity ratio was zero, hemin synthesis was not measurable, globin formation was depressed. In both radiated and starved animals the ratio of C^{14} activity of hemin to that of globin deviates considerably from the control values.

Effects of india ink injections in avitaminosis A. STELIOS C. SAMARAS (by invitation), NICHOLAS DIETZ, JR. (by invitation) and VICTOR E. LEVINE. *Dept. of Biological Chemistry and Nutrition, Creighton Univ. School of Medicine, Omaha, Nebr.* One hundred male rats were divided into several groups, some of which served as controls while others were allowed to develop the classical signs of vitamin A deficiency. Rats on the adequate stock diet and those on the vitamin A-deficient diet plus carotene tolerated injections of India ink. Rats on the vitamin A-deficient diet presented a sudden aggravation of the usual deficiency symp-

toms when injected subcutaneously with India ink. The rats injected in the afternoon, when examined the next morning, showed startling symptoms referable to the visual apparatus. They seemed nearly blind or totally blind, and could not find their food and water. Enophthalmos was marked, the decrease in the size of the eyeball being apparently due to loss of fluid. In vitamin A-deficiency blindness has a slow onset and is the end result of dryness, bacterial invasion and infection, bacterial damage or ulceration, and repair with formation of opacities. In vitamin A deficiency aggravated by blocking or irritating the reticulo endothelial system blindness occurs suddenly due to loss of physiological function, and is probably a depletion phenomenon. The phagocytosis induced by the introduction of the foreign body, India ink, may completely exhaust the vitamin reserve or may increase the metabolic demand for vitamin A to such an extent that hardly any of the small quantity yet available can be allocated to the retina for the rhodopsin-retinene cycle. Histological studies and analyses of tissues for carotene and vitamin A are in progress.

Relationship of purines, folic acid, and other principles in the nutrition of *Leuconostoc citrovorum* 8081. H. E. SAUBERLICH (introduced by W. D. SALAMON). *Laboratory of Animal Nutrition, Alabama Polytechnic Institute, Auburn, Ala.* Further investigations on the nutrition of *Leuconostoc citrovorum* 8081 has revealed that the unknown factor appears to be involved in purine metabolism. The organism was found to require for growth either xanthine, guanine, or hypoxanthine. Adenine, thymine, and uracil had no apparent activity when tested alone, but did have a sparing action on xanthine, guanine, or hypoxanthine. Increased amounts of anti-pernicious anemia preparations, liver concentrates, rat urine preparations, or vitamin B₁₂ concentrates could replace (in part at least) the requirements for guanine, xanthine, or hypoxanthine. High amounts of folic acid could, in the presence of purines, replace the unknown factor required by the organism. The omission of folic acid had no effect upon the response of the organism to the various concentrates of the growth principle. However, aminopterin at a level of 10 gamma/10 ml assay tube inhibited growth completely. The inhibition could be reversed by anti-pernicious anemia preparations, liver concentrates, rat urine preparations, or thymidine. Folic acid was effective only when extremely high amounts were used. Rats injected with folic acid or fed diets containing 5 or 10 mg of folic acid/kg excreted in the urine a compound(s) active for the growth of *Leuconostoc citrovorum*. Sulfaguanidine fed to rats along with the folic acid did not decrease the activity of the urine. The feeding of vitamin B₁₂ concentrates, ascorbic acid, or thymine in the place of folic acid in the

diets to rats did not cause an increase in the activity of the urine

Effect of low environmental temperature on thyroid function as studied with radioactive iodine H G SCHACHNER, Z S GIERLACH and A T KREBS (introduced by H JENSEN) *Medical Dept, Field Research Laboratory, Fort Knox, Ky* From studies with radioactive iodine, it was concluded by Leblond *et al* (Leblond, Gross, Peacock and Evans *Am J Physiol* 140 671-676, 1943-44), that "exposure of rats to cold (0° - 2° C) for various periods of time produces a thyroid stimulation which is doubtful after 1-3 days, definite after 7 days, maximal at 26 days, but absent after exposure for forty days" A reinvestigation of the problem seemed indicated to show how early stimulation occurs and compares with the long time interval Rats were exposed in individual cages to temperatures of 1° - 4° C and the uptake and organic binding of tracer and carrier doses of inorganic iodide after 1, 3, 7, 9, 26 and 60 days exposure were determined A definite increased uptake of iodine was shown in the 1-, 3-, 7- and 9 day group The results of these early time intervals will be compared with 26-, 40- and 60-day groups

A study of tryptophane metabolism using isotope tracer technique R W SCHAYER (by invitation), G L FOSTER, and DAVID SHEMIN *Dept of Biochemistry, College of Physicians and Surgeons, Columbia Univ, New York City* Tryptophane containing N^{15} in the indole nucleus has been synthesized and resolved into the D- and L- isomers Tryptophane containing C^{14} in the β -position of the side chain has also been synthesized After the intraperitoneal injection of N^{15} L-tryptophane into rats and rabbits, the isolated kynurenine, kyurenic acid and xanthurenic acid contained N^{15} having approximately the same concentration as the ring nitrogen of the tryptophane Similarly, N^{16} -labeled kynurenine produced xanthurenic acid in rats without dilution The 6-pyridone of N-methyl nicotinamide, isolated from rat urine with the aid of carrier after intraperitoneal injection of N^{15} DL-tryptophane, was found to have a small but significant N^{15} concentration In contrast to this finding, the 6-pyridone isolated after incubation of N^{16} DL tryptophane with rat liver slices, and after intraperitoneal injection of the C^{14} DL-tryptophane in rats, contained no excess isotope Hemin isolated from rats after injection of large quantities of N^{15} DL-tryptophane had an insignificant N^{15} concentration Studies are in progress on the fate of N^{15} indole, N^{15} L-tryptophane and N^{15} D-tryptophane in rats

Determination of uric acid in whole blood and plasma ARNOLD H SCHEIN and EMILY F RICE (introduced by HAROLD B PIERCE) *Dept of Biochemistry, College of Medicine, Univ of Vermont, Burlington, Vt* The determination of uric acid by

the Folin method (or by its various modifications) is beset with many difficulties which render uncertain the values obtained thereby Lack of specificity, inhibition of color development by various substances and low recoveries of added uric acid have proved to be a great hindrance to accurate estimation of uric acid in biological material Specificity can be increased by employing uricase (Blauch-Koch, Buchanan) Starting at this point we have investigated the conditions necessary for the accurate and precise determination of uric acid in blood and plasma It was found that pH control (pH 9.2—borate buffer) during color development is a requisite for good recoveries of uric acid Folin-Wu filtrates of many substances, notably proteins and amino acids which cause color inhibition do so partially by virtue of their depressing effect upon the pH of the color reaction True inhibitions of color development of the order of 10-20% caused by many amino acids in their expected normal (and abnormal) plasma concentrations, can be completely compensated by 'swamping' both the standards and the solutions containing inhibitors with adequate amounts of glycine Experiments upon blood and plasma in which these new modifications of the Folin method were employed revealed 90-95% recovery of added uric acid Recoveries of the same order of magnitude were obtained upon addition of known amounts of uric acid to uricase incubated blood and plasma (uric acid free) These results were checked by ultra violet enzyme spectrophotometry

Intermediary metabolism of phenylalanine labeled with C^{14} BERNARD SCHEPARTZ (by invitation) and SAMUEL GURIN *Dept of Physiological Chemistry, School of Medicine Univ of Pennsylvania, Philadelphia, Penna* Administration of DL-phenylalanine (labeled in the carboxyl and alpha positions) to phlorhizinized rats results in the appearance of C^{14} in the urinary ketone bodies as well as in the respiratory CO_2 Upon incubation of this type of phenylalanine with liver slices, acetoacetate labeled solely in the carboxyl group is obtained When ring-labeled phenylalanine (carbons 1, 3, 5) is administered to phlorhizinized rats, C^{14} appears in the respiratory CO_2 as well as in the acetone moiety of the urinary acetoacetate Incubation of ring-labeled phenylalanine with liver slices produces acetoacetate labeled chiefly in the terminal methyl group The aromatic ring of phenylalanine readily undergoes cleavage in the course of metabolism, the immediate precursor of acetoacetate being a four-carbon unit derived from the ring and side-chain Apparently no 2 carbon units are involved in this pathway It is apparent that the alpha carbon of phenylalanine becomes the carboxyl carbon of acetoacetate while either carbon atom 1 or 3 of the ring forms the terminal carbon of acetoacetate This furnishes direct proof that

the side chain of phenylalanine shifts to an adjacent ring carbon during the formation of ketone bodies

The quantitative determination of glycerylphosphorylcholine (GPC) in tissues GERHARD SCHMIDT, L HECHT (by invitation), N STRICKLER (by invitation) and S J THANNHAUSER *Tufts College Medical School, Boston, Mass* Trichloroacetic acid filtrates of tissues are freed from interfering substances by precipitation with mercuric acetate at pH 5 (GPC and choline remain quantitatively in the supernatant) Aliquots of the Hg free supernatant are precipitated with Reinecke salt before (A) and after (B) acid hydrolysis (N HCl, 20', 100°) The reineckates obtained from the majority of tissues can be analyzed colorimetrically without further purification, but in certain tissues (intestinal mucosa) a reprecipitation of the concentrated acetone solution of the reineckate with aqueous Reinecke salt is necessary in order to obtain the choline reineckate in well crystallized form The hydrolyzable choline (B-A) represents the choline group of GPC The following amounts of GPC (mg P/100 gm fresh tissue) were found in fresh beef organs liver 25, pancreas 15, submaxillaries 4, muscle, heart, brain, intestines negligible Free choline negligible in all fresh tissues After 3 hours' incubation, a strong increase in the amounts of GPC occurs in pancreas (40), and strong increases of free choline, but not of GPC, occur in kidney and intestines In incubated liver the amount of GPC remains practically unchanged, and no free choline appears in appreciable quantities

Factors concerned in the liberation of pteroylglutamic (folic) acid from its heptaglutamate by chick liver M L SCOTT (by invitation), C H HILL (by invitation), and L C NORRIS *Cornell Univ, Ithaca, N Y* Previous results from this laboratory have shown that under certain conditions the activity of the vitamin B₉ conjugase system in the livers from young chicks is increased by the addition of β -pyracin (4-pyridoxic acid) (*J Biol Chem* 158 291, 1945, *ibid* 160 265, 1945) In a continuation of these studies, it has been found that livers from day-old chicks, produced by hens whose diet contained no animal protein, were nearly devoid of vitamin B₉ conjugase activity Under these conditions the effect of added β -pyracin was variable On the other hand, the addition of certain concentrates derived from the alcohol-soluble material obtained in the preparation of a commercial liver extract produced marked increases in the liberation of folic acid from pteroyl-heptaglutamate This effect was further enhanced when both the concentrates and β -pyracin were combined In view of the suspected presence of small amounts of the antipernicious anemia factor in the liver concentrates, it was thought that

vitamin B₁₂ might be one of the factors required in the conjugase system Accordingly, experiments were conducted in which concentrates of this vitamin were added to the liver incubation system with and without β -pyracin Synergistic effects were also obtained between these two factors at a level of the vitamin B₁₂ concentrate which provided approximately 4 μ M of vitamin B₁₂ Preliminary work using crystalline vitamin B₁₂ have yielded similar results The results obtained in these studies indicate, therefore, that this vitamin is required in addition to β -pyracin in the enzymatic release of folic acid

Activation of purified prothrombin with sodium citrate WALTER H SEEGER and ARNOLD G WARE (by invitation) *Dept of Physiology and Pharmacology, Wayne Univ, Detroit, Mich* Purified prothrombin prepared by the method of Ware and Seegers (*J Biol Chem*, 174 565, 1948) is free of thromboplastin and Ae-globulin The protein, when dissolved in 30% sodium citrate solution, is transformed to thrombin At room temperature thrombin first begins to appear slowly after 16 hours, then rapidly for about 3 hours, and thereafter again more slowly The form of the activation curve suggests autocatalysis The prothrombin molecule apparently contains all of the necessary structural material for the formation of thrombin The activation with sodium citrate can be completely blocked with small amounts of 3,4,4'-triaminodiphenyl sulfone or with 2-hydroxy-4,4'-diaminodiphenyl sulfone All of the protein of the prothrombin preparation can be adsorbed on BaCO₃ The thrombin activity is not adsorbed on BaCO₃ Consequently purified prothrombin can be activated with sodium citrate, and any protein which is then not adsorbed on BaCO₃ must be thrombin alone or thrombin together with other parts of the original prothrombin This provides an easy method to prepare thrombin Moreover, all of the above facts are unusually valuable for gaining insight into the nature of prothrombin, its activation, and the nature of thrombin

The estimation of glycogen in liver and muscle SAM SEIFTER and SEYMOUR DAYTON (by invitation) *Dept of Biochemistry, Long Island College of Medicine, Brooklyn, N Y* Dieywood (*Ind Eng Chem, Anal Ed*, 18 499, 1946) described the use of anthrone for detection of carbohydrates, and Morris (*Science*, 107 254, 1948) suggested its use for the estimation of glycogen The present authors have employed the reagent in a simple direct method for glycogen in liver In this method 4 to 8 gm of liver (less may be used) are delivered into a weighed, graduated tube containing approximately 25 cc of 30% KOH, and the tube reweighed The tube contents are digested for 30 minutes in a boiling water bath, cooled, and made up to 35 cc with KOH Appropriate dilutions of the digest are

made with water (1 50, 1 250, etc.), and 5 cc aliquots are transferred to Evelyn tubes. While submerged in cold water, the tubes then receive 10 cc of 0.2% anthrone made up in 95% H_2SO_4 . 5 cc of standard containing 80 γ of glucose is similarly treated. All tubes are then heated for 10 minutes in boiling water, cooled, and read in the Evelyn photoelectric colorimeter at wavelength 620. The glycogen content of the liver is then calculated. When the glycogen content of liver or muscle is less than 0.6% this method is inapplicable due to interference of color produced by anthrone with the relatively increased protein contents of adequate aliquots. In these cases the glycogen may be first precipitated with alcohol, redissolved, and determined as above. The results agree with those obtained by the method of Good, Kramer and Somogyi.

Effects of ionizing radiation on the anaerobic CO_2 production and colony production in *saccharomyces cerevisiae* FREDERICK G. SHERMAN and HERMAN B. CHASE (introduced by P. H. MITCHELL) *Brown Univ., Providence, R. I.* Yeast was grown (48 hours at 30°C) in Reader's medium to which was added glucose 20 gm/liter and biotin, 2 micrograms/liter. Cells were washed twice with $\text{m}/15 \text{ KH}_2\text{PO}_4$ or supplemented Reader's medium, diluted to standard density and dispensed into lusteroid centrifuge tubes. One half the tubes were irradiated 30 minutes (90,000r at 3000r/min). A 200 kv therapy tube operated at 20 ma was used as the source. After irradiation cell suspensions were transferred to small flasks and incubated at 30°C for 2 to 24 hours. Aliquots were taken for plate counts and manometric estimation of anaerobic CO_2 production at stated intervals. Two to 4 hours after the beginning of irradiation the anaerobic CO_2 production (glucose or supplemented Reader's as substrate) is inhibited approximately 30% and about 85% of the irradiated cells are unable to form visible colonies. No inhibition of anaerobic CO_2 production was observed immediately after irradiation. Between 12 and 24 hours anaerobic CO_2 production on a per cell basis progressively declines suggesting that some 'injured' cells have further reduction in ability to ferment glucose, or have lost it entirely. Investigations by earlier workers on the effect of γ -radiation on enzyme systems *in vivo* indicate that fairly large doses have practically no effect in diminishing their activity (Wels and Osann, *Pflügers Arch.* 207: 156, 1925). Only with yeast grown on Reader's medium plus biotin have we been able to obtain consistent and reproducible inhibition of fermentation after irradiation.

The biological synthesis of serine from glycine PHILIP SIEKEVITZ (by invitation), THEODORE WINNICK and DAVID M. GREENBERG *Div of Biochemistry, Univ of California Medical School, Berkeley, Calif.* The *in vitro* synthesis of serine

from glycine has been demonstrated both in rat liver slices and homogenates by means of tracer experiments with C^{14} -labeled glycine. The reaction proceeds anaerobically. Employing-carboxyl-labeled and methylene-labeled glycine, it has been shown that the carboxyl-carbon of glycine appears in the carboxyl-group of serine, while the methylene-carbon of glycine appears in both the alpha and beta carbons of serine. Aerobically, the C^{14} concentration of the beta-carbon was approximately 40% that of the alpha-carbon. Anaerobically, it was only 5%. Sakami (*J Biol Chem* 176: 995, 1948) has shown that formate reacts with glycine to form serine, the formate carbon appearing in the beta carbon of serine. We have now shown that this formate, at least in part, may be derived from glycine itself. Rat liver slices were incubated in nitrogen with radioactive glycine and non-radioactive formate, the latter at twice the concentration of the former. One flask (I) contained methylene-labeled glycine, the other (II) had carboxyl-labeled glycine. Carrier formate was added, steam distilled, and oxidized to CO_2 (Osborn, Wood, and Werkman, *Anal Ed, Ind Eng Chem* 5: 47, 1933). Glyoxylic acid is not oxidized to CO_2 by this method. The CO_2 obtained from flask (I) was radioactive, that from flask (II) was not, showing that formate is derived from the alpha carbon of glycine. The dilution of radioactivity in the beta-carbon indicates a non glycine source of formate, which is more active anaerobically than aerobically.

Oxygen consumption of 'Killer' and 'Sensitive' stocks of *paramecium aurelia*, variety 4 D. H. SIMONSEN (by invitation) and W. J. VAN WAGEN-DONK *Dept of Zoology, Indiana Univ., Bloomington, Ind.* Two genetically diverse stocks occur within variety 4 of *Paramecium aurelia*. The 'killer' stocks produce a toxic substance, 'paramecin', which kills 'sensitive' animals in a typical manner. The two types are determined genetically. The killer stocks possess the killer gene K which can support the multiplication of the self-duplicating cytoplasmic factor, 'kappa', but cannot initiate its production *per se*. Kappa in turn controls the production of paramecin. Sensitive animals may be those having the genotype KKK without kappa, or those with the recessive allele kk. Sensitive animals are killed in a typical fashion when mixed with killer animals, when placed in culture fluid in which killers have grown, or when exposed to a dilute brew prepared by crushing killer animals. Measurements of the rates of oxygen consumption of these stocks were made using the Cartesian diver micro-respiration technique. The stocks used for comparison belonged to the same mating type and were grown under the same conditions of feeding. The live animals were suspended in sterile 'exhausted' lettuce infusion in the divers. Rates of oxygen consumption were determined over a period of 8-10 hours at 27° .

Killer animals were found to respire at a higher rate than sensitive animals. The respiration of sensitive animals while under the influence of paramycin was followed. Pertinent data will be presented.

Serum lipides of Eskimos. Effect of a high fat diet (pemmican) and of fasting. R. G. SINCLAIR, G. M. BROWN (by invitation) and L. B. CRONK (by invitation). *Depts. of Biochemistry and Medicine, Queen's Univ., Kingston, Canada.* As part of a clinical and biochemical study of the Eskimos on Southampton Island in the Eastern Canadian Arctic, lipides were determined in the serum of 126 persons. Regardless of age, sex and absorptive state, the average values, in mg/100 ml, were: Total fatty acids, 329 ± 103 (S.D.), lipide P, 9.9 ± 2.0 , total cholesterol, 173 ± 29 , free cholesterol, 47.5 ± 9.4 . Free cholesterol amounted to $27.7 \pm 3.0\%$ of total. The molar ratio of phospholipide to total cholesterol was 0.72 ± 0.09 . A palpable hepatomegaly was observed in about $\frac{1}{3}$ of the Eskimos. The average values for the serum lipides in this group were the same as in those without enlarged livers. In a small group of 2 men and 2 women who subsisted for 6 days exclusively on pemmican (75% of the calories from beef fat), the levels of all lipides increased considerably. A subsequent 4 day fast by 3 subjects caused a further appreciable increase in all lipides—total fatty acids, 55% increase, lipide P, 30%, total cholesterol, 15%. A similar fast by a man who had been on his customary diet of meat and bannock caused an increase in total fatty acids but not in lipide P, total or free cholesterol. Little or no ketonuria developed after 6 days on pemmican, the subsequent fast caused a definite ketonuria.

The lipotropic action of threonine. S. A. SINGAL, V. P. SYDENSTRICKER (by invitation) and JULIA M. LITTLEJOHN (by invitation). *Univ. of Georgia School of Medicine, Augusta, Ga.* While studying the nicotinic acid-tryptophan relationship in rats on 9% casein ration containing 5% fat and 0.2% cystine and choline, yellowish livers were observed at autopsy. Upon analysis the liver lipids were 16.0%. Supplementary nicotinic acid, tryptophan, valine, histidine, phenylalanine or serine were without effect. The addition of threonine reduced the liver lipids to 5.1%. Because of the growth depressing action of threonine under these experimental conditions (*J. Biol. Chem.* 176: 1063, 1948), nicotinic acid or tryptophan was added to this diet under which conditions growth was satisfactory and the liver lipids were 6.6%. When choline was increased to 1.0%, a similar reduction of liver lipids was observed. That the lipotropic action of threonine was not the result of increased food intake was demonstrable in paired-feeding experiments. Here the liver lipids of rats on the casein ration supplemented with tryptophan was 14.4% as compared to 5.9% when threonine was also included. When the dietary fat was increased to 40%, the liver lipids

were 21.8 and 10.1% respectively. The livers of rats on an amino acid diet simulating the 9% casein ration supplemented with tryptophan contained 17.0% lipids. Supplementary threonine reduced the lipids to 5.3%. When threonine was omitted from the entire ration, the rats lost weight and the liver lipids were only slightly above normal.

Unlikelihood of specific long range forces in immunologic and enzymatic reactions. S. J. SINGER (introduced by L. ZECHMEISTER). *Gates & Crellin Laboratories of Chemistry, California Inst. of Technology, Pasadena, Calif.* Rothen has performed experiments (*J. Biol. Chem.* 168: 75, 1947) in which antibody is adsorbed on antigen films which are apparently covered with inert barriers, and other experiments (*J. Am. Chem. Soc.* 70: 2732, 1948) in which enzymatic reactions occurred despite apparent separations of enzyme and substrate proteins. From these he concludes that specific long range forces are involved in immunologic and enzymatic reactions. By 3 approaches, we have obtained evidence that holes in the barrier films are responsible for the effects observed. 1) Certain cellulose derivatives used as inert barriers reduce the adsorption of antibody on films of bovine serum albumin considerably. Ethyl cellulose films cast from ethylene dichloride solution are particularly effective, but those cast from acetone solution permit increased antibody adsorption. This demonstrates the importance of the physical state of the barrier films. 2) With the electron microscope, we find that antibody is concentrated in clumps when adsorbed on formvar films above bovine serum albumin layers, although antibody is evenly distributed when adsorbed directly on the antigen, and the surfaces of the formvar films without antibody are uniform. This suggests that reaction occurs through holes in the formvar films. 3) Intervening formvar films permit antibody directed against the p-azophenylarsonic acid group to be adsorbed on p-azophenylarsonic acid conjugated proteins. Since the work of Landsteiner, Pauling and collaborators, among others, makes it extremely likely that these conjugated protein systems react by a short range mechanism, these experiments indicate that the antigen and antibody molecules actually come into contact through holes in the polymer films.

Inhibitors of the L-amino acid oxidase of snake venoms. THOMAS P. SINGER and EDNA B. KEARNEY (by invitation). *Dept. of Biochemistry, Western Reserve Univ. School of Medicine, Cleveland, Ohio.* The L-amino acid oxidase of snake venoms, apparently a yellow enzyme, is inhibited by flavin analogues. The analogue, isoriboflavin, which has proved inhibitory to every yellow enzyme tested in this laboratory, inhibits the L-amino acid oxidase of moccasin venom 50% at 0.0004M concentration. Riboflavin itself inhibits appreciably even at

0.00004M concentration 0.002M atabrine decreases the activity by 50%. A group of polyvalent anions are even more inhibitory to this enzyme. Notable among these are inorganic phosphate and arsenate, which completely inactivate the enzyme at 0.001M or lower concentrations, under appropriate conditions. An extensive study of this enzyme in various venoms revealed that the oxidases of pit vipers are highly sensitive to phosphate, those of true vipers less sensitive, and those of colubrine venoms insensitive. While the action of riboflavin analogues on the enzyme is instantaneous, the effect of phosphate and arsenate increases with time and also with temperature, pH, and the molarity of phosphate, it is inversely related to the protein concentration. Monovalent anions and organic bases protect the enzyme from the action of phosphate, while substrates and riboflavin analogues protect in catalytic amounts. The inhibition is not of the competitive type. Metaphosphate, pyrophosphate, organic phosphates, arsenite, molybdate, sulfate, and thiosulfate are less inhibitory, but ferricyanide is as effective as phosphate. The kinetics of the reaction have been studied in detail, and a combination with the enzyme protein is suggested as a probable mechanism.

Phosphomannose isomerase MILTON W. SLEIN (introduced by GERTY T. CORI) *Dept. of Biological Chemistry, Washington Univ. School of Medicine, St. Louis, Mo.* Lohmann's phosphohexose isomerase catalyzes the reaction, glucose-6-phosphate \rightleftharpoons fructose-6-phosphate. A purified isomerase which can be prepared from rabbit muscle or from yeast does not act on mannose-6-phosphate. The latter was prepared by allowing crystalline yeast hexokinase to act on mannose in the presence of ATP. It was found that rabbit muscle contains a separate enzyme which together with Lohmann's isomerase establishes an equilibrium between the three phosphorylated hexoses in the approximate ratio of glucose 56, fructose 29, and mannose 15%.

Isolation of the staphylococcus stimulatory factor(s) (SSF) NATHAN H. SLOANE (by invitation) and RALPH W. MCKEL *Dept. of Biological Chemistry, Harvard Medical School, Boston, Mass.* *Staphylococcus albus* grows maximally on a synthetic medium but with a lag phase of 12-16 hours. Growth is stimulated with extracts of vegetable, animal and bacterial products. Antipernicious anemia liver extract is inactive. The active factor(s) in deproteinized plasma and urine are non-dialyzable, heat stable, moderately stable to acid and alkali, stable to proteolytic enzymes, soluble in methanol (pH 3), insoluble in common organic solvents, precipitable with silver (pH 6) and inactivated by ninhydrin. Combining dialysis and silver precipitation the activity in human urine is concentrated 200- to 400-fold (nitrogen) with almost 100% recovery. The material is quite unstable upon

standing but activity can be restored by reaction with glutathione. The electrophoretic pattern (pH 8.6) shows five peaks, the mobilities of two being within the range of α_1 and α_2 globulins, the other peaks had mobilities greater than the normal plasma constituents. Using bovine plasma, deproteinizing with heat (about pH 5), dialyzing and precipitating with silver, the activity is concentrated 140- to 400-fold (0.06-0.021 mg N/μ) with 50-100% recovery. The electrophoretic pattern (pH 8.6) shows 4 peaks, the mobilities of 2 being within the range of α_1 and α_2 globulins. This concentrate gave a positive orcinol hexose test. Treatment of this concentrate with chloroform-isoamyl alcohol (pH 6.6) causes a 90-100% loss of activity, which is restored with glutathione or cysteine. The degree of purification is 850- to 1700-fold (nitrogen). The purified material is non-dialyzable. Human plasma and its protein fractions (Cohn *et al.*) were studied and fraction 1V-4 contained the greatest concentration of SSF.

Studies on transaminase in germinating seeds and its relation to protein synthesis BETSY PATTERSON SMITH (by invitation) and HAROLD H. WILLIAMS *Dept. of Biochemistry and Nutrition, Cornell Univ., Ithaca, N. Y.* The relative changes in the amounts of glutamic-alanine and glutamic-aspartic transaminase and protein were determined during the first 120 hours of germination of seeds of *Graminae* (barley and corn), *Leguminosae* (pea and wax bean), and *Cucurbitaceae* (pumpkin and squash). All the seeds tested began germination with the same low level of transaminase, but the amount synthesized during growth ranged from 0.3 units in the pea to 1.33 units in barley for the glutamic-aspartic transaminase and from 0.20 units in squash to 0.70 units in barley for the glutamic-alanine enzyme. In almost every case the glutamic-aspartic transaminase increases more rapidly than the glutamic-alanine enzyme. In general, the rate of transaminase formation during germination was greater than that of protein as judged by the increased number of units of the enzyme per milligram of protein nitrogen. Supplying the germinating seeds with a nutrient solution caused an increased rate of synthesis of both transaminase and protein, but the change is greater for the enzyme than for protein. Thus it is indicated that transamination is limited in its role in the plant to the interconversion of amino acids and keto acids, and that the new amino acids formed may have several possible fates, only one of which is the synthesis into protein.

Optical and side-chain specificity of leucine aminopeptidase EMIL L. SMITH and W. J. POLGLASE (by invitation) *Laby for the Study of Hereditary and Metabolic Disorders and the Depts. of Biochemistry and Medicine, Univ. of Utah School of Medicine, Salt Lake City, Utah.* The side chain

specificity of this enzyme is not absolute, a number of aliphatic amino acid amides are attacked at different rates. These rates were estimated from the first-order coefficients obtained with two different preparations of the enzyme, one having 20 times the activity of the other. Nevertheless, the relative rates for the 2 preparations for the following compounds were identical: L-leucinamide (100), DL-norleucinamide (100), DL-norvalinamide (80), DL- α -n-aminobutyrylamide (44), L-alaninamide (6.3), and glycylamide (0.34). Only the L forms are hydrolyzed, D-leucinamide, D-leucylglycine, and D-leucyl-L-tyrosine are completely resistant to the enzyme. L-Leucyl-L-alanine is split about 25 times faster than L-Leucyl-D-alanine. Both bonds of L-alanyl-L-leucinamide are rapidly hydrolyzed, and the rate is about 850 times greater than the action on D-alanyl-L-leucinamide where only the terminal amide linkage is split. β -Alanyl-L-leucinamide is hydrolyzed even more slowly than is the latter compound. An interpretation of the action of this enzyme has been made in terms of the poly-affinity theory. The substrate combines with the protein through the metal (Mn^{++} or Mg^{++}) at the free amino group and at the nitrogen of the sensitive amide or peptide linkage. The residue which bears the carbonyl of the sensitive bond has its side-chain bound directly to the protein, the affinity of the protein for the side-chain is a function of the mass of the aliphatic group. The enzymatic specificity thus depends on correct steric relationships of the side-chain and of the groups which are bound to the metal.

Interrelationship between chloramphenicol (chloromycetin) and enzymatic systems. GRANT N. SMITH and CECILIA WORRELL (introduced by O. D. BIRD). *Research Laboratories, Parke, Davis & Co., Detroit, Mich.* Studies of the action of chloramphenicol on enzymatic systems have been conducted to determine if the action of the new antibiotic can be explained on the basis of an inhibitory effect on enzymes and enzyme systems. Members of the following classes of enzymes: esterases, carbohydrases, amidases, proteolytic enzymes, iron oxidases, copper oxidases, dehydrogenases and miscellaneous enzymes were subjected to the action of chloramphenicol. Three methods were used to evaluate these actions. The first method used was to test the action of the antibiotic on highly purified preparations of the isolated enzymes. The other 2 methods consisted of studies on the intact enzymes present in bacterial cells using the plate technique developed by Dufrenoy *et al.* and the broth culture technique. No indications of inhibitory action of chloramphenicol could be detected in any of the systems studied. The effect of various enzymes and enzymatic systems on chloramphenicol have also been studied to determine if the antibiotic can be destroyed by enzymatic conversion to an inactive

form. Both isolated enzymatic systems and enzymes liberated into the culture media by intact organisms have been tested on the antibiotic. Results have shown that a partial breakdown of chloramphenicol is possible.

Phosphorus metabolism of molds. I. Uptake and transformation of orthophosphate by penicillium chrysogenum Q176. J. F. SNELL (by invitation) and W. H. PETERSON. *Univ. of Wisconsin, Madison, Wis.* Uptake of orthophosphate by *P. chrysogenum* Q176 in shaken flask and stirred jar fermentations on various media has been determined. Although there was considerable variation, the most rapid and complete uptake occurred in stirred jar fermentations on corn steep media. Mycelia varied in total phosphorus content (0.7%–5%, dry basis) depending upon aeration, age, media, etc. In a given fermentation, for example, the dried mycelium contained 3.1% at 3 days, reached a maximum of 4.7% at 6 days and fell to 2.1% at 8 days. On media containing a large excess of orthophosphate, higher amounts accumulated in the mycelium. From 30–60% of the total phosphorus was extracted by 4% trichloroacetic acid in 2 hours at 0°. The proportion of labile phosphorus to total phosphorus in the extract (0–6%) was affected by medium age of mycelium, method of extraction, etc. A typical extract of mycelium showed a $P_0:P_1:P_{>1}$ ratio of 25:6:69. Inorganic pyrophosphate and metaphosphate have been isolated from the extract, in confirmation of the work of Mann. Further components of this extract have been studied. No adenosine triphosphate has been obtained from the mycelium by procedures which gave good preparations from rabbit muscle in parallel experiments. Studies on the rate of turnover of the forms of phosphorus have been limited by inadequate fractionation procedures. Fractionation has not been successful by schemes proposed to date in the literature. Some fractionation has been achieved, however, and turnover studies utilizing P^{32} are in progress.

Aqueous dispersions of fat-soluble vitamins. ALBERT E. SOBEL, ABRAHAM ROSENBERG (by invitation), ROY GEDULDIG (by invitation), ELI ENGEL (by invitation), MICHAEL WEST (by invitation) and BENJAMIN KRAMER. *Dept. of Chemistry and Pediatrics, Jewish Hospital of Brooklyn, Brooklyn, N. Y.* Post-partum mother rats were fed vitamin A in aqueous dispersion or the same A in oily solution. The suckling rats of the aqueous group showed higher vitamin A stores. The same preparations had been previously fed nursing women. Distinctly higher rises of A were found in the milk of the aqueous group. Thus, one might conclude that with aqueous dispersions (without and with other vitamins, Vifort) there is an increased total secretion of milk vitamin A. The higher blood levels obtained with aqueous dispersions fulfill the theoretical requisites for greater diffusion to the site of

milk production To produce controlled high levels and overcome absorption problems, conditions were developed for intravenous injection of aqueous dispersions of fat-soluble vitamins No hemolysis occurs in whole blood when concentration of the dispersing agent is 0.1% or less Bearing this in mind, aqueous dispersions of vitamins A and E were intravenously injected into rabbits with no pathologic effects That aqueous dispersions may help in the absorption of other fat-soluble vitamins besides A was shown by studies with E Higher absorption in normal adults occurred when aqueous dispersions of vitamin E were given orally as measured by vitamin E absorption curves

Cystine and methionine content of portal blood plasma JAMES D SOLOMON (by invitation), and HAROLD D WEST *Dept of Biochemistry, Meharry Medical College, Nashville, Tenn* The cystine and methionine levels in the plasma of portal and peripheral blood were determined before and after administration of these amino acids to the dog Since failure of cystine to rise in the peripheral blood plasma after feeding this amino acid has been demonstrated, it appeared that a study of its content in the portal blood plasma might throw further light on the absorption of this amino acid Cystine together with methionine was fed by gavage to the tracheal-cannulated dog under ether anesthesia Blood samples were taken from portal and femoral veins before feeding and at intervals of one and one-half and three hours Cystine and methionine were determined in the plasma tungstate filtrates before and after hydrolysis by use of microbiological methods The control samples from the portal and femoral (peripheral) vessels showed no increase in the microbiologically available methionine or cystine following hydrolysis of the tungstate filtrates In samples taken after administration of these acids to the animal there was no significant rise in the level of the cystine in either case, but there was significant rise in the methionine level in portal blood accompanied by a much greater increase in its content in peripheral (femoral) blood When these filtrates were hydrolyzed there was a considerable increase in cystine but the increase in methionine content of the portal blood plasma was not significant, in the peripheral blood filtrate hydrolysates there was no increase in the content of cystine or methionine

Electrophoretic studies of the soluble proteins of rabbit liver S SOROF (by invitation) and P P COHEN *Laby of Physiological Chemistry, Univ of Wisconsin, Madison, Wis* Reproducible electrophoretic patterns have been obtained using high speed supernates of homogenates of perfused rabbit liver All experiments were carried out in a cold room maintained at 4°C Aliquots of whole liver, or homogenate, or supernate from the same rabbit liver were used for comparative electrophoretic ex-

periments The following factors were investigated with reference to their effects on the electrophoretic patterns homogenization medium, pH stability, time stability, effect of freezing and thawing, and ultracentrifugation From the large number of studies carried out, the following emerged as significant findings 1) the electrophoretic pattern of rabbit liver supernate consists of four principal components The component in liver supernate with the mobility of rabbit serum albumin electrophoretically represents 4% of the soluble liver proteins 2) The soluble proteins of rabbit liver are unstable, unless special measures are taken Certain of these alterations are reversible 3) Exposure to air causes changes principally in two components Cysteine, thioglycollate and glutathione are each capable of reversing the aerobic changes in one of these two components However, in order to reverse the aerobic changes in the other component, glutathione is required Ascorbate is ineffective toward both components 4) In the case of first mentioned component, present evidence indicates that protein sulfhydryl groups are involved in a reversible reaction

Composition of brain lipids in male and female rats WARREN M SPERRY, FLORENCE C BRAND (by invitation), and MERRILL WEBB (by invitation) *Dept of Biochemistry, New York State Psychiatric Inst, New York City* Weil reported (*Growth*, 7: 257, 1943) that brains of female rats, 90-180 days old, contained more 'ether-soluble phospholipids (cephalin)' and less 'alcohol-soluble (lecithins), pyridine-soluble (galactolipids), and -insoluble lipids (sphingomyelins)' than male brains Such a sex difference should manifest itself in the P:choline ratio of the brain lipids In a few preliminary measurements, reported previously (*Proc Div Biol Chem, Am Chem Soc*, 50C Sept, 1948), a small, but not statistically significant difference in this ratio was observed However, further studies under more carefully controlled conditions the same average P:choline ratio was obtained in rats of both sexes Following are the average values, with standard deviations, for various lipid constituents, determined in this investigation, expressed as percentage of fresh brain, from 125-156 days-old male and female rats, respectively Choline, 0.462 ± 0.019 , 0.469 ± 0.027 , P, 0.245 ± 0.018 , 0.248 ± 0.011 , cholesterol, 1.89 ± 0.14 , 1.89 ± 0.11 , glycosphingosides, 2.47 ± 0.13 , 2.45 ± 0.11 Average stoichiometric ratios calculated from these data are P:choline, 2.07 ± 0.15 , 2.07 ± 0.19 , cholesterol:choline, 1.28 ± 0.10 , 1.27 ± 0.13 , P:cholesterol, 1.62 ± 0.08 , 1.64 ± 0.07 , P:glycosphingosides, 2.63 ± 0.13 , 2.68 ± 0.22 No support for the hypothesis that there is a sex difference in the lipid composition of the brain may be derived from these data The findings will be com-

pared with values determined in the same way in rats of other ages

Combined ultraspectrographic and chemical studies in cerebrospinal fluids (CSFs) in normal and pathologic conditions M SPIEGEL-ADOLF and H T WYCKS (by invitation) *Depts of Colloid Chemistry and Neurosurgery, Temple Univ Medical School and Hospital, Philadelphia, Penna* Systematic ascorbic acid determinations in CSFs (*Federation Proc* 7 No 1) were made according to Robinson and Stotz In 20 cases 2 ascorbic acid standards were used The average error was $0.17 \pm 1.83\%$ Ascorbic acid was determined simultaneously with the ultraspectrographic examinations The extinction coefficients E_{CSF} at $265 \text{ m}\mu$ were corrected for the corresponding values of ascorbic acid E_A and proteins E_P $D = E_{\text{CSF}} - (E_A + E_P)$ was determined in 60 cases of functional and organic neurological conditions The lowest D values ($0.0-1.4$) were observed in psychoneurotics, old brain injuries, initial stages of brain affections The highest D values (from $0.61-2.16$) occurred in brain tumors, frequent grand mal attacks, spinal block, compression of the cord, recent cerebral concussion Intermediate values were found in milder convulsive states, herniated discs, head traumata without unconsciousness and brain tumors of specified histological and/or anatomical properties In an attempt to analyze the substances producing the D values micro-Kjeldahl determinations of the non-protein-nitrogen content were carried out in CSFs showing low and on samples showing high D values The NPN values of the latter exceeded the supposedly normal values by an average of 50% The above results seem to indicate that the selective absorption of pathologic CSFs at $265 \text{ m}\mu$ is not explained by the ascorbic acid and protein content alone Presence of nucleic acids and/or their cleavage products is suggested by the optical behavior NPN determinations as well as the clinical findings support this interpretation

Relative importance of plasmatic and vascular factors of hemostasis in the hemorrhagic diathesis of liver dysfunction MARIO STEFANINI (introduced by A J QUICK) *Dept of Internal Medicine, Univ of Roma, Italy, and Dept of Biochemistry, Marquette Univ School of Medicine, Milwaukee, Wis* Of 200 patients with evident liver dysfunction, 30 (15%) presented spontaneous hemorrhages The effectiveness of the hemostatic mechanism was studied in all, in an attempt to evaluate the relative importance of vascular and plasmatic factors of hemostasis in the pathogenesis of the hemorrhagic manifestations of these cases Capillary fragility was variably increased in all patients Plasma prothrombin activity was below 50% of normal in 53.3% of the cases, and below 20% in 23.3% Plasma fibrinogen level varied from 90-356 mgr % being, therefore, constantly above the critical level

of 60 mgr % established by Pinniger and Prunty Changes in antithrombin activity of plasma were too inconsistent for definite conclusions Therefore the diminution of capillary resistance was predominantly important in the pathogenesis of spontaneous hemorrhages in this series of liver patients Furthermore, among the remaining 170 patients not presenting hemorrhages, capillary resistance was found diminished in 2 cases only, and prothrombin activity below 20% of normal in 9, so it appears that even a serious defect of the coagulation mechanism did not determine spontaneous hemorrhages when capillary resistance was normal Hypoprothrombinemia and diminution of the capillary resistance found in liver disorders may present a common pathogenetic factor because of their association in about 50% of cases As vitamin K normalizes the diminished capillary resistance of reversible liver dysfunction, this common factor might be represented by a defect of utilization of the vitamin by a diseased liver

Effect of various adsorbants on the components of the prothrombin complex MARIO STEFANINI (by invitation) and ARMAND J QUICK *Dept of Biochemistry, Marquette Univ School of Medicine, Milwaukee, Wis* Oxalated plasma when treated with $\text{Ca}_3(\text{PO}_4)_2$, $\text{Al}(\text{OH})_3$, BaSO_4 , or $\text{Mg}(\text{OH})_2$ will not clot on recalcification even in the presence of excess thromboplastin These agents adsorb varying quantities of the components of the prothrombin complex and also some fibrinogen By carefully regulating the quantity of adsorbant, a fairly quantitative separation especially of component B, the factor which diminishes in dicumarol poisoning, can be achieved The best agent is $\text{Ca}_3(\text{PO}_4)_2$ since in the proper concentration (0.005 M) it adsorbs component B completely, but removes only a trace of the labile factor and fibrinogen The action of BaSO_4 is similar Both of these adsorbants are unable to remove component B from citrated plasma, therefore no decrease in prothrombin activity occurs on mixing citrated plasma with either of these adsorbants The prothrombin time of citrated plasma is prolonged to infinity by $\text{Al}(\text{OH})_3$ and $\text{Mg}(\text{OH})_2$ Citrate therefore does not block the adsorption of component B by these agents Neither $\text{Al}(\text{OH})_3$ nor $\text{Mg}(\text{OH})_2$ are as selective as $\text{Ca}_3(\text{PO}_4)_2$ for they adsorb appreciable amounts of the labile factor, some fibrinogen, and probably other factors that are associated with coagulation This explains why the prothrombin time curve constructed by diluting plasma with alumina treated plasma is similar to the curve using saline as diluent, whereas the curves obtained with BaSO_4 and $\text{Ca}_3(\text{PO}_4)_2$ treated plasmas as diluents are not

Combination of wool protein with strong bases JACINTO STEINHARDT and ETHEL M ZWISER (by invitation) *Dept of Chemistry, Massachusetts*

Inst of Technology, Cambridge, Mass Earlier work with 2 proteins, wool and egg albumen, has shown that their titration curves, obtained with different strong acids, differ widely in position on the pH axis. This effect is due to combination of the proteins with anions as well as hydrogen ions, and the differences between titration curves permit calculation of the relative affinities for protein of the anions. The effect of added salt on the titration is, in part, another manifestation of combination with anions. Since the effect of salt on the acid titration is exactly paralleled by its effect on titration with bases, these proteins must bind cations also. It is now shown that titration curves of wool at 0°C with 10 strong monovalent bases also exhibit wide differences. As with anions, the affinity of cations for protein increases with increasing molecular dimensions. Among organic cations of the same weight, asymmetric ions produce much the larger shift. Unlike the effects of anions, which are uniform over the entire acid curve, the effect of cations is more marked on the same portion of the titration curve which is affected by formaldehyde, i.e., the part due to lysine. The maximum shift in position of this part of the titration curve, obtained with tetradecyltrimethyl ammonium hydroxide, exceeds two pH units. Marked effects on other portions of the curve are shown only by asymmetric ions larger than the hexyltrimethyl ammonium ion. Explanations of this distinction are suggested, and effects on the stability of the protein will be described.

Conversion of S³⁵ homolanthionine to S³⁵-cystine in the rat JACOB A. STEKOL and KATHRYN WEISS (by invitation) *Lankenau Hospital Research Inst and Inst for Cancer Research, Philadelphia, Penna*. We reported that a mixture of isomers of homolanthionine is available to rats for growth purposes on a diet free of cystine but with minimal amounts of methionine. These results were interpreted as indicating the conversion of one or more isomers of homolanthionine to cystine *in vivo* (*J Biol Chem* 175:405, 1948). To secure a proof for the hypothesis we synthesized S³⁵-homolanthionine and fed it to young rats mixed with the diet (amino acid mixture diet) which was free of cystine but with 0.2% of methionine. After the rats grew for some time on the S³⁵ homolanthionine containing diet, the hair was clipped off, hydrolysed, and pure cystine was isolated and its radioactivity was measured. The product had a high radioactivity. These data establish beyond doubt the availability of the sulfur of homolanthionine for the synthesis of cystine *in vivo*.

Metabolism of hydroxyproline MARJORIE R. STETTIN *Dept of Biological Chemistry, Harvard Medical School, and Division of Nutrition and Physiology, Public Health Research Inst of The City of New York, New York City*. The amino acid hydroxyproline was synthesized in such a way as

to contain about 30 atom % excess N¹⁵. The synthetic mixture of 4 isomers was fractionated into the two DL forms. The DL(a) form, containing the naturally occurring l(-) hydroxyproline, was fed to 2 rats for 3 days and the distribution of N¹⁵ in the carcass, excreta, and a number of isolated amino acids was studied. The isotope analysis of the hydroxyproline isolated indicated that the dietary hydroxyproline was incorporated into the body proteins of the rat. The proline isolated contained only a trace of N¹⁵, indicating that hydroxyproline is not converted to proline to any appreciable extent in the rat. This is in contrast to the previously observed extensive biological oxidation of proline to hydroxyproline. These findings are in accord with other indications that proline and hydroxyproline are not metabolically equivalent.

d-Aspartic oxidase of rabbit kidney and liver J. L. STILL and M. V. BUELL (introduced by D. E. GREEN) *Inst for Enzyme Research, Univ of Wisconsin, Madison, Wis*. Rabbit kidney and liver contain an oxidase which catalyzes specifically the oxidation by molecular oxygen of d-aspartate to oxaloacetate according to the equation: d-Aspartate + O₂ → oxaloacetate + H₂O₂. A stable preparation of this enzyme can be prepared by homogenizing the tissue, centrifuging off the insoluble residue, then removing the precipitate formed at pH 5.4 and finally making an acetone powder of the clear supernatant fluid. This preparation contains little if any of Krebs' d-amino acid oxidase. Unlike the d-amino acid oxidase the aspartic oxidase is insensitive to benzoic acid in M/300 concentration. The liver and kidney cyclophorase preparations at the 3rd residue stage contain significant amounts of the d-aspartic oxidase. Under appropriate conditions the complete oxidation of d-aspartate to CO₂ and H₂O can be accomplished. Fluoride and the presence of some member of the citric acid cycle are essential for the complete oxidation. Aspartate can be synthesized by incubating the cyclophorase system with oxaloacetate and NH₃ under aerobic conditions. The basic reaction appears to be: 3 oxaloacetate + NH₃ → citrate + aspartate + CO₂. Under the aerobic conditions of the experiment citrate undergoes further oxidation. The oxidase does not oxidize l-aspartate, d-glutamate or other d-amino acids.

Metabolism of 16-ketoestrone and 16-keto-α-estradiol in man BENJAMIN F. STIMMEL, ARTHUR GROLLMAN, and MAX N. HUFFMAN *Recs-Stealy Medical Research Fund, Ltd, San Diego, Calif, and the Depts of Pharmacology and Experimental Medicine and of Biochemistry, Southwestern Medical College, Dallas, Texas*. Colorimetric urinary estrogen excretion data on men after injection of 16-ketoestrone and 16-keto-α-estradiol indicate that man is capable of converting these compounds in part to estrinol, but not to estrone and estradiol.

Zinc-hydrochloric acid hydrolysis of aliquots of the post-injection urine yields greatly augmented estrogen titers in the estradiol and estriol fractions of our (Stimmel *J Biol Chem* 162 99, 1946) liquid chromatogram. There is evidence that 16-ketoestrone appears in the urine following injection with either of these compounds and that reduction of it to 16-ketoestradiol by zinc-hydrochloric acid hydrolysis of its conjugate in urine, accounts for the augmented estrogen titers obtained by this method of hydrolysis. These studies with exogenous estrogens therefore provide a working model in support of the hypothesis of Smith and Smith (*Endocrinology* 28 740, 1941) that more highly oxidized estrogens than those presently known are excreted in the urine and that these may be converted to more active forms during hydrolysis by the addition of zinc dust.

Microbiological assay of vitamin B₁₂ by *Lactobacillus leichmannii* E. L. R. STOKSTAD, A. C. DORNBUSH (by invitation), A. L. FRANKLIN (by invitation), C. E. HOFFMANN (by invitation), B. L. HUTCHINGS and T. N. JUKES, *Lederle Laboratories Division, American Cyanamid Co., Pearl River, N. Y.* *Lactobacillus leichmannii* 313 (ATCC 7830) was reported to respond to the crystalline anti-pernicious-anemia factor (vitamin B₁₂). Further studies showed that thioglycolic acid increased the growth response produced by vitamin B₁₂. This was shown to be primarily due to protection of vitamin B₁₂ against destruction during autoclaving of the samples with the medium. Protection was also accomplished by the addition to the medium of other reducing agents such as ascorbic acid or certain natural supplements that had been freed such as ascorbic acid or certain natural supplements that had been freed of thymidine and vitamin B₁₂. Similar results were obtained by adding the sample aseptically. Thioglycolic acid did not increase the response due to thymidine, presumably because thymidine is more stable and is not destroyed during autoclaving. *L. leichmannii* 313 was found to require a growth stimulant produced during autoclaving of the medium, as very little growth was obtained with a sterile-filtered or steamed medium even in the presence of vitamin B₁₂. This growth stimulation could alternatively be supplied by methyl glyoxal or thioglycolic acid, suggesting an effect due to a reduction in oxygen tension. Similar results were obtained with another strain, ATCC 4797, of *L. leichmannii*, which was found to grow more slowly and to have a lower requirement of vitamin B₁₂ for half-maximum growth.

Non-participation of acetyl phosphate in the fixation of formate into pyruvate HAROLD STRECKER (by invitation) and HARLAND G. WOOD, *Dept. of Biochemistry, Western Reserve Univ. School of Medicine, Cleveland, Ohio*. It has been

previously demonstrated with *E. coli* extracts that synthetic acetyl phosphate was not an active intermediate in the dissimilation of pyruvate. The possibility that biologically produced acetyl phosphate might differ from the synthetic material was investigated in the following manner. C¹⁴ carbonyl labeled pyruvate was synthesized and incubated with cell free extracts of *E. coli*. Fermentation was allowed to proceed until 30-50% of the original pyruvate was determinable as acetyl phosphate by the Lipmann hydroxylamine method. The residual pyruvate was then diluted approximately tenfold with non-isotopic pyruvate, and C¹⁴ formate equivalent to the acetyl phosphate formed was also added for measurement of the extent of reversibility. An aliquot was withdrawn for analysis and degradation and the remainder was allowed to ferment. If the biologically formed high count acetyl phosphate was in dynamic equilibrium with pyruvate in accordance with the reaction $\text{CH}_3\text{COCOOH} \rightleftharpoons \text{CH}_3\text{COOP}(\text{OH})_2 + \text{HCOOH}$, the final residual pyruvate should show an increase of specific activity in the carbonyl group comparable to that of the carboxyl group as introduced from the formate. No such increase was obtained although C¹⁴ was introduced into the carboxyl group. It is therefore concluded that acetyl phosphate is not an intermediate in the formate exchange reaction. That exchange of formate may not occur through the phosphoroclastic reaction is indicated by experiments with aged enzyme. Pyruvate was not broken down as measured by acid production in bicarbonate yet exchange with formate occurred at the same rate as with a fresh preparation.

Effect of dihydroxyphenylalanine on enzymatic digestion M. X. SULLIVAN and S. STEPHEN SCHIAFFINO (by invitation), *Chemo-Medical Research Institute, Georgetown Univ., Washington, D. C.* In 1913, Torquato Torquati isolated a nitrogenous pyrocatechol complex from the germ of the broad bean (*Vicia faba*) and Guggenheim extracted a similar material from the broad bean pods and identified it as dihydroxyphenylalanine. Since then this compound has been found in a number of legumes. Some years ago we had occasion to study the lentil which had been found of poor nutritive value and we found that the lentil contained dihydroxyphenylalanine as determined colorimetrically. The same color reaction was positive with other legumes such as the Georgia velvet bean known to contain dihydroxyphenylalanine. Accordingly a study was made of the effect of dihydroxyphenylalanine on peptic and tryptic digestion of egg albumin. By the procedure described by Callvary (*J Biol Chem* 102 73, 1933) no inhibition of peptic digestion was found when dihydroxyphenylalanine was added at various levels to the digestion mixture, albumin, pepsin held at pH 2. In tryptic

digestion, however, dihydroxyphenylalanine has an inhibitory action. This was proved by estimating the amount of dye released from a dyed protein during 4-16 hours of digestion by trypsin and also by the amount of methionine released and estimated by the McCarthy, Sullivan colorimetric procedure. On estimating at different levels, it was found that 25 mg of dihydroxyphenylalanine to 1 gm of albumin had the same effect as 50 mg, a very marked inhibition. Even with 10 mg and 5 mg of 'dopa' there was 59 and 52% inhibition respectively in the amount of methionine liberated.

Reactions of hemoglobin with aliphatic and inorganic nitrate and nitrite esters F WILLIAM SUNDERMAN and HAROLD WOOSTER (by invitation) *Mellon Institute, Pittsburgh, Penna., and Cleveland Clinic, Cleveland, Ohio*. The quantitative aspects of methemoglobin formation have been studied following incubation at 38°C of washed, laked human erythrocytes with solutions of potassium nitrate, butyl nitrate, diethyleneglycol dinitrate, nitroglycerine, potassium nitrite, and amyl nitrite. All of the nitrate compounds studied produce 2 molecules of methemoglobin per molecule of nitrate in accordance with the equation $\text{NO}_3^- + 2\text{Fe}^{++} (\text{hemoglobin}) \rightarrow \text{NO}_2^- + 2\text{Fe}^{+++} (\text{methemoglobin})$. Our analyses reveal a disappearance of nitrate without a corresponding increase in nitrite. Hemoglobin solutions incubated with potassium nitrite for 5 hours at 38°C yield 2 molecules of methemoglobin per molecule of nitrite, when incubated for 24 hours they yield more than 3 molecules of methemoglobin. If nitrites were to act directly as oxidizing agents, they would theoretically produce only 1 methemoglobin molecule per molecule of nitrite. The finding of higher ratios, therefore, suggests that nitrite probably first forms nitrate, which then reacts with hemoglobin to produce methemoglobin. Our studies indicate that amyl nitrite differs from other compounds studied in that it may either oxidize hemoglobin or reduce methemoglobin.

Activation of phosphoglucumutase E SUTHERLAND (by invitation), T POSTERNAK (by invitation), and C F CORI *Washington Univ., School of Medicine, Biological Chemistry Dept., St. Louis, Mo*. Various samples of glucose-1-phosphate (G-1-P), prepared enzymatically or chemically, were found to differ greatly in the rate of conversion to glucose-6-phosphate (G-6-P) by yeast or crystalline muscle phosphoglucumutase. Addition of active to inactive G-1-P raised the rate of conversion of the latter to that of the former. A possible explanation was the suggestion of Leloir and coworkers (*Arch. Biochem.* 19: 339, 1948) that glucose-1,6-diphosphate (G-1,6-P) was an activator in catalytic amounts according to the equation $\text{G-1-P} + \text{G-1-P} \rightleftharpoons \text{G-6-P} + \text{G-1,6-P}$. G-1,6-P was synthesized by interaction of crystalline α -1-bromo-2,3,4-triacetyl-6-diphenylphosphonoglucose with silver

phosphate, followed by catalytic hydrogenation to remove phenyl groups and partial hydrolysis with hydrochloric acid in methanol to remove acetyl and two hexosephosphate groups. The substance was isolated as the barium salt, more soluble in cold than in hot water, and gave correct analytical values for labile and stable phosphate, and for reducing power after hydrolysis. Cysteine (0.01M) was used to insure full activity of the enzyme. Cysteine could be replaced by heavy metal reagents such as diphenylthiocarbazon, 8-hydroxyquinoline, and histidine. Both the yeast and muscle enzyme were strongly activated by these reagents or protected by them when traces of zinc were added. The cysteine-activated enzyme did not convert G-1-P to G-6-P unless G-1,6-P was added in catalytic amounts, confirming Leloir's scheme. Half maximal activity of the enzyme was obtained when the concentration of the G-1,6-P was about 2×10^{-6} molar. A sample of G-1-P containing only 0.1% G-1,6-P will therefore be fully active in the usual reaction mixture containing 6×10^{-3} molar G-1-P.

Specificity of liver glucose-6-phosphatase MARJORIE A SWANSON (introduced by CAMILLO ARTOPI) *Dept. of Biochemistry, Bowman Gray School of Medicine, Winston-Salem, N. C.* It has been known for some time that liver extracts hydrolyze hexosemonophosphates, but the number of enzymes concerned and their degree of specificity are uncertain. In the present investigation, extracts variously prepared from rat liver were found to liberate inorganic phosphate from glucose-1-phosphate, fructose-1,6-diphosphate, ATP, and glycerophosphate at a low rate, and from glucose-6-phosphate and fructose-6-phosphate at a much higher rate. Isoelectric precipitation at pH 5.5 increased the glucose-6-phosphatase activity/mg of protein about threefold. Simultaneously the ability to split glucose-1-phosphate and fructose-1,6-diphosphate was lost, and the activity toward fructose-6-phosphate was diminished. The decrease in the rate of splitting fructose-6-phosphate paralleled the decrease in hexose isomerase activity, suggesting that its presence is necessary for the liberation of phosphate from fructose-6-phosphate. Thus it might logically be concluded that there is in the liver a specific glucose-6-phosphatase which, in the absence of phosphoglucumutase and hexose isomerase, hydrolyzes neither glucose-1-phosphate nor fructose-6-phosphate. Glycerophosphatase activity accompanied glucose-6-phosphatase (in the ratio of 1.5 to 1.6) through several attempts at purification. Presumptive evidence for the non-identity of these two enzymes was obtained on the basis of differential fluoride inhibition, lack of competitive inhibition, and different pH-activity curves.

Changes in the cholesterol concentration of rat liver homogenates during incubation LEON SWELL (by invitation) and C R TREADWELL *Dept. of*

Biochemistry, George Washington Univ, School of Medicine, Washington, D C Normal rat livers were homogenized with 0.154M phosphate buffer of pH 7.2 and diluted to definite volume with buffer. All manipulations were performed at 0–3°C. Fifteen cc aliquots were transferred to test tubes, mixed with 100 mg of sodium glycocholate and placed in a shaker at 38°C. Duplicate 1 cc samples were removed at zero hours and after various periods of incubation. The free and ester cholesterol were determined by a modification of the method of Hess (*Federation Proc* 6:260, 1947). During the first 2 to 4 hours the total cholesterol concentration decreased markedly, then decreased slowly until 6 hours had elapsed. With continued incubation the total cholesterol increased over that observed at 6 hours. After 8 to 12 hours the concentration approximated the zero hour value. Still longer incubation up to 36 hours usually gave values above the original level. The trend was toward a decrease in both free and ester cholesterol from 0 to 6 hours and an increase from 6 to 24. Studies of the influence of pH on these changes indicated that while the initial phase of decrease occurs over a range of 5.8 to 8.0, the increase in concentration occurs only from pH 6.8 to 7.2. Other experiments show that the observed changes in cholesterol concentration are not caused by microorganisms or volume changes. The effects of different temperatures and of the addition of possible precursors of cholesterol on these changes have been studied.

Isolation of a crystalline heat stable trypsin inhibitor from lima beans HENRY TAUBER V D. *Research Laboratory, U S Public Health Service, U S Marine Hospital, Staten Island, N Y* A crude concentrate, containing at least two proteinase inhibitors, was prepared by a modification of Kunitz' (*J Gen Physiol* 29:149, 1946) procedure for the initial purification of crystalline soybean trypsin inhibitor. Ground lima beans were extracted with 0.25N H₂SO₄. The proteinase inhibitors were adsorbed on Bentonite, eluted with 10% aqueous solution of pyridine, precipitated by (NH₄)₂SO₄, dialyzed salt-free, and 3 volumes of acetone added for precipitation. From this precipitate a crystalline heat stable trypsin inhibitor was isolated as follows: the precipitate was dissolved in 1% NaCl solution. In order to remove impurities, a small amount of Bentonite was added and the mixture was shaken for 15 minutes. The clear filtrate was dialyzed for about 20 minutes against ethanol, applying occasional stirring. Small microscopic crystals formed. The solution was allowed to crystallize overnight at room temperature. The crystals were dissolved in 1% NaCl. Acetone was added till the mixture was slightly turbid. The solution was allowed to crystallize overnight at room temperature. Two recrystallizations of this material resulted in colorless octahedra of much larger size.

This crystalline material is a globulin. It is precipitated by acetone, ethanol and trichloroacetic acid. It does not dialyze through cellophane. It powerfully inhibits crystalline trypsin. Proteolysis and milk clotting by chymotrypsin are moderately effected. The proteolytic and milk-clotting action of pepsin are not inhibited. This trypsin inhibitor somewhat resembles Kunitz' crystalline soybean trypsin inhibitor. In contrast to his inhibitor, however, the crystalline lima bean inhibitor is exceptionally heat stable. The soybean inhibitor is destroyed on short boiling.

Molecular weight of human fetal hemoglobin JOHN FULLER TAYLOR and RICHARD L SWARM (by invitation) *Washington Univ School of Medicine, Dept of Biological Chemistry, St Louis, Mo* We have measured the sedimentation and diffusion constants of fetal oxyhemoglobin (HbO₂) prepared from cord blood taken from normal full-term infants. The erythrocytes were washed with saline solution and laked with toluene. Adult HbO₂ solutions were similarly prepared from bank blood. Sedimentation velocity was measured in a 'Spinco' analytical ultracentrifuge at 20 to 30°. Diffusion was followed in a Claesson cell at 2°. Results have been corrected to water at 20°. We observed for fetal HbO₂ an S_{20,w} of 3.98 at 0.9% protein, and 4.01 at 0.5%, and for adult HbO₂ an S_{20,w} of 4.00 and 3.99 respectively. Essentially identical S values were obtained for fetal HbO₂ and HbCO in dilute phosphate buffer. M. A. Andersch, D. A. Wilson, and M. L. Menten (*J Biol Chem* 153:301, 1944) had reported values of 2.6 to 3.0 for 0.5% fetal hemoglobin. An average diffusion constant, D_{20,w}, of 6.6 cm² sec⁻¹ was obtained for 1% fetal HbO₂ in 1% NaCl. D values of 6.3 to 6.9 for adult hemoglobin have been reported in the literature. The identity in the sedimentation constants and the agreement in the diffusion constants of fetal and adult HbO₂ indicate that the hemoglobins from either source have the same molecular weight under the conditions of our experiments.

Bound coenzymes of the cyclophorase complex of rabbit kidney and liver L. J. TEPLY (introduced by D. E. GREEN) *Institute for Enzyme Research, Univ of Wisconsin, Madison, Wis* The cyclophorase gel of rabbit kidney or liver at the third residue stage (exhaustively washed with dilute salt solution) contains considerable amounts of the following coenzymes in bound form: adenine nucleotides, pyridine nucleotides, acetylation coenzymes, flavin dinucleotide, pyridoxal phosphate and diphosphothiamine. It also contains appreciable amounts of bound biotin and folic acid. The adenine nucleotides exist in the form of AMP, ADP, and ATP. By various devices AMP can be converted largely to ATP and vice versa. During storage of the enzyme at 0° for several days or at 35° for 24 hours the adenine nucleotide level declines. The pyridine

nucleotides are a mixture of CO_I and CO_{II} in approximately equal amount. The relative proportion of these two coenzymes remains fairly constant under a variety of conditions. With aging of the enzyme there is a steady decline of the level of pyridine nucleotides. The bulk of the acetylation coenzyme of rabbit liver and kidney appears to be bound up with the protein of the cyclophorase complex. All the above coenzymes are released from the cyclophorase gel in varying degrees by treatment with boiling water or 5% trichloroacetic acid. A crude barium salt fraction prepared from the neutralized trichloroacetic acid extract contains mainly pyridine nucleotides, flavin dinucleotide, the acetylation coenzyme, adenine nucleotides and inorganic phosphate.

Studies of growth factors in liver extract using paper partition chromatography GARSON H TISHKOFF, H T PEELER, ALEJANDRO ZAFFARONI, HENRY TESLUK, and L C NORRIS (introduced by ELMER H STOTZ) *Depts of Pathology and Biochemistry, School of Medicine and Dentistry, Univ of Rochester, Rochester, N Y, and School of Nutrition, Cornell Univ, Ithaca, N Y* Recent investigations by Daniel, Peeler, Norris, and Scott (*J Biol Chem*, in press) have demonstrated the presence of two unidentified factors in purified liver extract which are distinct from streptogenin but required by *Lactobacillus casei* for growth. These investigators have also demonstrated that a correlation exists between the antipernicious anemia activity of the extract and the growth response of *Lactobacillus casei* to one of these factors (APA factor) in the presence of an excess of the second factor ('whey' factor). In order to establish the nature of these factors, and as a possible method for their isolation in pure form, liver extract was fractionated using paper partition chromatographic technique and the individual fractions assayed for the APA factor and 'whey' factor.

Preparation of hyaluronate from some mammalian sources SIBYLLE TOLKSDORF (by invitation), JAMES W CASSIDY (by invitation), CAROL BONSAI (by invitation) and D ROY McCULLAGH *Dept of Biochemistry, Schering Corporation, Bloomfield, N J* Human umbilical cords, bovine synovial fluid, bovine vitreous humor and hog belly skin have been processed by various methods in investigating the production of hyaluronic acid. Modifications of the Rogers method (*Biochem J* 39 1945) have been employed and in general his technique has been used successfully except in the case of hog belly skin. However, it has been found that certain substances which interfere with the assay of testicular hyaluronidase are frequently present in such hyaluronate preparations. We have found that these impurities can be removed by washing the crude mucin clot with 0.2% acetic acid before separating the proteins by precipitation with chloroform. A

simpler method has been employed for the production of hyaluronate from umbilical cords for assay purposes. The macerated cords were heated with water to 80°C to precipitate proteins. Impurities were removed by adsorption on bentonite or other agents. The hyaluronates form a white powder when precipitated with acetone and dried with acetone and ether. No success has been attained in applying this procedure to other starting materials. Elementary chemical analysis would suggest that the polysaccharide from all these sources is essentially the same. The characteristics of the hyaluronate molecule which govern its viscosity must be due to different aspects of the molecular structure than those which control its capacity to cause turbidity with acidified proteins. This is attested to by the fact that preparations of similar purity show no quantitative relationship between the two phenomena.

Biochemical studies on the livers of chicks receiving graded levels of pteroylglutamic acid JOHN R TOTTER, WILLIAM MARTINDALE (by invitation), MARION MCKEE (by invitation), CECILIA K KEITH (by invitation), and PAUL L DAY *Dept of Biochemistry, School of Medicine, Univ of Arkansas, Little Rock, Ark* Groups of day-old White Leghorn chicks were given a purified diet (KEITH ET AL *J Biol Chem* 176 1095, 1948) supplemented with 0, 5, 10, 20, 40, 80, 200, and 1000 μg of pteroylglutamic acid (PGA) per 100 grams. An additional control group received a commercial starter diet. At the end of 4 weeks the birds were killed. The livers were analyzed for 1) PGA, using *Streptococcus faecalis* and conjugases from hog kidney and chicken pancreas, 2) conjugase, 3) desoxyribose nucleic acid and 4) ribose nucleic acid. The PGA levels in the livers indicated that storage of excess vitamin did not occur until the dietary level exceeded 40 $\mu\text{g}/100\text{ gm}$. The liver PGA freed by autolysis was approximately the same as that determined with conjugases from hog kidney or chicken pancreas. The conjugase levels of the livers appeared to be unrelated to either the dietary level of PGA or the nucleic acid content of the livers. Desoxyribose nucleic acid was found to be somewhat low in the chicks receiving no dietary PGA, but the differences among all other groups were of doubtful significance.

Cholesterol esterase of pancreatin C R TREADWELL, R S YAMAMOTO (by invitation), and NORMAN P GOLDSTEIN (by invitation) *Dept of Biochemistry, George Washington Univ School of Medicine, Washington, D C* Preliminary to an investigation of the significance of cholesterol and its esters we have attempted to evaluate the optimum conditions for demonstrating the activity of the enzyme. Commercial pancreatin was used as a source of cholesterol esterase. In most of the previous work natural materials, such as serum, have

been used to supply the substrate. In these experiments synthetic cholesterol oleate has been used as the substrate. Technical difficulties were encountered in the preparation of a stable emulsion of the ester. When various emulsifying agents were tested, singly and in combination, the most efficient found was phosphate buffer containing albumin and bile salts. When cholesterol oleate was emulsified in this mixture and the emulsion incubated at 38°C with shaking, the solution was homogeneous in respect to the ester for periods up to 48 hours as shown by analysis of duplicate aliquots. When 1 cc of a 20% suspension of pancreatin in 50% glycerol and 14 cc of the substrate mixture were incubated for 24 hours, 45% hydrolysis was obtained. The rate of hydrolysis was constant for 24 hours. The optimum pH was found to be approximately 7. Heat inactivation experiments indicated that the enzyme was completely inactivated by heating at 65°C for 1 hour. The degree of hydrolysis was proportional to the concentration of the enzyme.

Quantitative aspects of coprecipitation in the purification of substances isolated in tracer studies. SIDNEY UDENFRIEND (by invitation), ALBERT S. KESTON (by invitation), NORA LEVITAS (by invitation) and MILTON LEVY, *Dept. of Chemistry, New York Univ. College of Medicine, New York City*. In the isotopic derivative method we encountered, in several instances, considerable difficulties in the elimination of impurities by crystallization. The basis of the difficulty was a distribution of the impurity between crystals and solution as though between immiscible solvents and may be formulated $K = I_s/C_s/I_c/C_c$ where I and C are the amounts of impurity and carrier in supernatant (subscript s) and crystals (subscript c). The amount of purification achieved in a single crystallization is greater the larger is K and the greater the loss of carrier in the supernatant. Addition of the non-isotopic analogue of the impurity to dilute its activity has no advantage as long as the above formulation holds and it has been found to hold in instances from an impurity level of 0.0001% to 5%. Crystallization of DL leucine containing S-35 methionine gave $K = 2.5$. For alanine with glycine as the impurity $K = 1.5$. Practically the same constants are found for the same amino acids as pipsyl derivatives. Thus it is not necessarily advantageous to prepare different derivatives in the course of purification. As an example of the import of this phenomenon only by 200 recrystallizations, sacrificing 5% of the remainder at each, would a system with $K = 1.5$ reach a level of 1% of the original impurity. Coprecipitation must be considered in evaluating any 'constant isotope concentration' attained by crystallization. Chromatographic and countercurrent solvent extractions techniques are more dependable in this respect.

Action of streptomycin in tissue homogenates

W. W. UMBREIT and N. E. TONHAZY (by invitation) *Merck Institute for Therapeutic Research, Rahway, N. J.* Previous reports have demonstrated that one of the actions of streptomycin is to inhibit the condensation between oxalacetate and pyruvate in susceptible strains of *Escherichia coli*. Inasmuch as this is an important reaction in animal cells, the question arises as to why streptomycin is able to enter the animal body, kill or inhibit the susceptible bacteria contained in it, without comparable harm to the animal. The condensation of oxalacetate and pyruvate is largely localized in the mitochondrial fractions, whose activity may be preserved by homogenizing in isotonic KCl or isotonic sucrose. Using isotonic homogenates from rat liver and rat kidney, it was demonstrated that streptomycin in concentrations of 30–60 γ /ml had no effect upon the oxalacetate-pyruvate reaction. However, when the concentration was increased to 300 γ /ml inhibition was frequently obtained. Inhibition of this reaction could be demonstrated for low levels of streptomycin if the homogenate and the streptomycin were incubated in the cold for two hours. The circumstances of these experiments are such as to suggest that streptomycin will inhibit the oxalacetate-pyruvate condensation in the animal as well as in the bacteria but that in the animal there is a permeability barrier at the cell wall and at the mitochondria which prevents the streptomycin from reaching the enzymes in the animal cell concerned with catalyzing this reaction.

Conversion of isotopic pyruvate to oxalacetate by pigeon liver. M. F. UTTER and MARY T. CHENOWETH (by invitation) *Dept. of Biochemistry, School of Medicine, Western Reserve Univ., Cleveland, Ohio*. Although it has been assumed that the formation of oxalacetate in the Wood-Werkman reaction is accomplished by the carboxylation of pyruvate, previous studies have dealt only with CO_2 without identification of the other component. In the present work, the incorporation of labeled pyruvate into oxalacetate has been compared with the incorporation of C^*O_2 to determine the nature of the immediate precursor of oxalacetate. Carboxyl labeled pyruvate was synthesized from acetyl-bromide and $Cu_2(C^*N)_2$ via pyruvonitrile and pyruvamide. Oxalacetate was decarboxylated by a pigeon liver preparation in the presence of pyruvate and C^*N_2 and the residual oxalacetate separated and purified as the mercurous salt. The oxalacetate was analyzed for isotope content in the two carboxyl groups since one group originates from CO_2 and the other from the pyruvate carbonyl. Results indicate that the fixation of pyruvate in oxalacetate occurs with certain enzymatic preparations but is not correlated with the fixation of CO_2 . Some enzymatic preparations that fix CO_2 very rapidly are inactive on pyruvate. In contrast to the marked stimulation of CO_2 fixation caused by ATP, a 1

pyruvate fixation occurs it is relatively unaffected by ATP. The foregoing findings lead to the tentative conclusion that pyruvate is not the immediate precursor of oxalacetate. Preliminary results show that labeled pyruvamide can be substituted for pyruvic acid in the reaction mixture and is also incorporated in a compound resembling oxalacetate. The mechanism is under investigation.

Isotopic studies of the biosynthesis of nucleic acid components II allantoin JEROME D VALENTINE (by invitation), SAMUEL GURIN and D WRIGHT WILSON *Dept of Physiological Chemistry, School of Medicine, Univ of Pennsylvania, Philadelphia, Pa*. It has been established that the carboxyl carbon of glycine is a source of carbon 4 in the uric acid excreted by the pigeon. In order to determine what role glycine plays in the biosynthesis of purines in mammals, glycine labeled in the carboxyl position with C^{14} was mixed with a stock diet and fed to young albino rats for a period of 10 days. From pooled 24-hour collections of urine, allantoin was isolated, purified and analyzed. All samples of allantoin were found to be radioactive, the specific radioactivity increasing gradually to a maximum on the 10th day. By degradation of allantoin to glyoxylic acid and urea the C^{14} was found in the glyoxylic acid fraction, corresponding to carbons 4 and 5 of the allantoin molecule. Allantoin isolated after giving carboxyl labeled sodium acetate intraperitoneally to 5 rats over a 5-day period was found to be very weakly radioactive. It would appear that this compound is either not directly utilized as such for purine synthesis or that it is directed into other metabolic pathways. These results are of interest in view of the fact that much of the carboxyl carbon of acetate is incorporated into carbons 2 and 8 in the uric acid excreted by the pigeon.

Inactivation of stilbestrol in alkali RAYMOND VANDERLINDE (by invitation) and W W WESTERFELD *Dept of Biochemistry, Syracuse Univ College of Medicine, Syracuse, N Y*. The inactivation of stilbestrol that occurs on standing in an alkaline solution results from a dehydrogenation of the stilbestrol to isodienestrol and a subsequent ring closure to indenestrol. Both of these products have been isolated from reaction mixtures. A nearly quantitative conversion to indenestrol was obtained when 0.8 mg of stilbestrol per cc of 0.8N NaOH stood at room temperature for 30 days. Isodienestrol and small amounts of unchanged stilbestrol were the principal products obtained when 1 mg of stilbestrol per cc of 0.02N NaOH stood at room temperature for 14 days. Isodienestrol is approximately 1/700 as active estrogenically as stilbestrol, indenestrol is at least 1/10 as active as stilbestrol. The relative decrease in estrogenic potency of the original stilbestrol solution will obviously depend upon the proportions of the three

main constituents in the final solution, and this varies with the conditions of inactivation.

Antigenic transformation in *paramecium aurelia* under the influence of proteolytic enzymes W J VAN WAGTENDONK *Dept of Zoology, Indiana Univ, Bloomington, Ind*. Within stock 51 of variety 4 of *Paramecium aurelia* 6 antigenically diverse strains have arisen (strains A, B, C, D, E and G). Each of these 6 types is inherited under standard conditions of culture. Differences in antigenic type do not depend on differences in genes but on cytoplasmic differences. These cytoplasmic factors are subject to environmental influences. Exposure to dilute antiserum, high or low temperature, brings about a transformation in antigenic type to any one of the possible types in this stock. The new antigenic type is inherited true to type, as long as the cultures are grown under standard conditions (Sonneborn *Scientific Monthly* 67:154, 1948). Five strains of *P. aurelia* (stock 51, variety 4) have been exposed to the action of trypsin and chymotrypsin at 27° for 12 and 24 hours. After exposure single isolations were grown for 8 fissions at 20°, 27° and 32°, and the antigenic type of the resulting clones determined. Under these conditions, strains 51A, 51B and 51G very rarely transformed into another type. Types 51C, 51D and 51E gave rise to a large variety in types. The susceptibility to trypsin and chymotrypsin of the latter three types is correlated with their instability under other external conditions.

Influence of biliary obstruction upon liver protein regeneration HARRY M VARS, COLIN C FERGUSON (by invitation) and CHARLES S ROGERS (by invitation) *Harrison Dept of Surgical Research, Schools of Medicine, Univ of Pennsylvania, Philadelphia, Pa*. Groups of male Wistar rats, previously protein-depleted for a period of 14 days, were subjected to partial hepatectomy (70%) and to simultaneous high ligation and division of the common bile duct. Postoperatively these animals were fed a 10% protein, low fat diet and were then killed on the 2d, 4th, eighth and 14th days. Control groups, only partially hepatectomized, were paired with the above rats. Total nitrogen balances were determined. Following death the amounts of new liver protein were measured, together with liver mass (wet and dry), glycogen and total lipid. Histological examination of all livers was made. At all periods postoperatively it was found that the biliary-obstructed rats not only had livers of greater mass but livers containing greater amounts of new liver protein than did the controls. Undoubtedly a portion of this protein increment is ductal in origin, and some may be present in the increased fluid content of the obstructed livers as plasma or lymph. However, estimation of the ductal proliferation as seen on histological examination and estimation of the protein associated with the

increased fluid indicate that liver protein regeneration occurred in the biliary-obstructed rat to a degree almost equal to that in the unobstructed pair-fed animal. Counts of parenchymal cell mitoses in both groups were approximately equal.

Rat liver fructokinase. CARL S. VESTLING, URSULA IRISH (by invitation), AUGUSTA K. HIRSCH (by invitation) and NORMAN H. GRANT (by invitation). *Division of Biochemistry, W. A. Noyes Laboratory of Chemistry, Univ. of Illinois, Urbana, Ill.* A study of the phosphorylation of glucose and fructose by rat liver homogenates has been carried out. It has been found that systems which phosphorylate fructose very effectively are quite inert to glucose. Addition of numerous materials (DPN, HDP, phosphocreatine, insulin, various phosphatase inhibitors and others) fails to allow phosphorylation of glucose at a rate at all comparable to that encountered with fructose. The Nelson procedure (*J. Biol. Chem.* 153: 375, 1944) and that of Roe (Browne and Zerban, *Sugar Analysis*, p. 961, 1941) have been employed in studying sugar disappearance. Slightly hypertonic phosphate buffer homogenates of livers from fasted rats have been used in this work. The complete systems contain ATP, $MgCl_2$, α -ketoglutarate or glutamate, substrate and homogenate. The effect of NaF has been studied. In certain experiments liver slices have been substituted for homogenates with essentially similar results. The oxidation of α -ketoglutarate or glutamate by these systems greatly improves the phosphorylating capacity. When glucose-1-phosphate, glucose-6-phosphate, or fructose-6-phosphate is incubated in rat liver systems, about one-fifth reappears as 'apparent glucose' and none as fructose. When a beef brain hexokinase preparation, which will phosphorylate both glucose and fructose, is added to a rat liver system, the combined system phosphorylates both glucose and fructose effectively. The combined system phosphorylates about twice as much glucose as the brain hexokinase alone. Boiling the brain hexokinase extract abolishes this effect.

In vitro utilization of C^{14} labeled acetate and pyruvate by rat diaphragm muscle. CLAUDE A. VILLEE, OLOF H. PEARSON (by invitation) and A. BAIRD HASTINGS. *Dept. of Biological Chemistry, Harvard Medical School, Boston, Mass.* Diaphragm muscle from normal, diabetic and adrenalectomized rats was incubated, using the technique of Gemmell, in a medium containing 0.04M sodium phosphate, 0.005M $MgCl_2$, 0.08M NaCl, and either carboxyl labeled C^{14} acetate or carbonyl labeled C^{14} pyruvate, 10 mM/l, initial pH, 6.8. A half diaphragm was placed in each Warburg vessel, to one of each pair of vessels 0.5 U insulin/ml medium was added. The diaphragms were incubated for 2 hours in an atmosphere of oxygen. The CO_2 collected in the center well was precipitated as $BaCO_3$, plated

and counted with an end window Geiger tube. Samples of the media before and after incubation were analyzed for pyruvate and lactate, and the amount of glycogen in the diaphragm before and after incubation was estimated. The metabolism of acetate to CO_2 in diabetic diaphragm was decreased to 35% of normal and this decrease was unaffected by the addition of insulin. Insulin had no effect on the metabolism of acetate to CO_2 in normal diaphragm. Experiments on the effect of adrenalectomy and on the metabolism of labeled pyruvate are underway and will also be reported.

Anesthesia with methylal in mice and dogs. ROBERT W. VIRTUE. *Division of Anesthesiology, Dept. of Surgery, State Univ. of Iowa, Iowa City, Iowa.* Exposure of mice to concentrations of 7% methylal ($CH_3-O-CH_2-O-CH_3$) in air was followed within 10 minutes by loss of reflexes producing a condition compatible with surgical anesthesia. Increasing the concentration to 17.5% methylal produced respiratory arrest. The anesthetic index was therefore 2.5. The corresponding index for ethyl ether was 2.0. Twenty-five% methylal in 0.9% sodium chloride solution was injected intravenously into dogs. Surgical anesthesia was produced with blood concentrations of methylal between 109 and 235 mg %. After injection of sufficient methylal to produce respiratory arrest the blood methylal values varied between 265 and 453 mg %, and one hour later the blood methylal values ranged between 99 and 295 mg %. As has been consistently observed during ether anesthesia, concentrations of blood glucose rose considerably during methylal anesthesia, the carbon dioxide combining power diminished, and the blood urea values increased slightly. Recovery of both mice and dogs from anesthesia with methylal was much slower than from anesthesia with ether, probably due to slower elimination of methylal because of its greater solubility in water.

Chromatographic separation of ribonucleotides and its application to the study of ribonucleic acid structure. ERNST VISCHER (by invitation), BORIS MAGASANIK (by invitation), and ERWIN CHARGAFF. *Dept. of Biochemistry, College of Physicians and Surgeons, Columbia Univ., New York.* The ribonucleotides derived from yeast ribonucleic acid, viz. adenylic, guanylic and cytidylic acids, can be separated from each other and also from muscle adenylic acid by chromatography on filter paper with isobutyric acid (saturated with water) as the solvent in a suitably maintained NH_3 atmosphere. The separated components are fixed on the paper as the uranyl salts and demonstrated by the conversion of the latter to brown uranyl ferrocyanide. Parallel undeveloped chromatograms serve for the extraction of the adsorbates with M phosphate buffer of pH 7.1 and the spectrophotometric estimation of the separated nucleotides by proce-

dures similar to the recently described method for purines and pyrimidines (Visseher and Chargaff *J Biol Chem* 176 703, 1948) The recoveries ranged from 90 to 100% If the distance of the yeast adenylic acid adsorbate from the starting point is taken as 100, muscle adenylic acid is 75, cytidylic acid 60, and guanylic acid 40 Alkaline hydrolysates of yeast ribonucleic acid exhibited 3 zones of adsorption which in their positions on the chromatogram and in their absorption spectra corresponded to guanylic, cytidylic and adenylic acids, respectively, accounting for a total of 75-85% of the nucleic acid used The quantitative distribution of the nucleotides thus determined following the degradation by various means of ribonucleic acids of yeast and of mammalian tissue will be discussed with particular emphasis on the bearing of these studies on the problem of nucleic acid structure

Function of the system, glutamic acid-glutamine, in brain metabolism HEINRICH WAELSCH, PAULA SCHWERIN (by invitation) and S P BESSMAN (by invitation) *Depts of Biochemistry, N Y State Psychiatric Institute and Columbia Univ, New York City* The protein-free filtrate of brain (rat, mouse, rabbit, calf) contains about 160 mg glutamic acid and 60 mg glutamine/100 gm tissue The concentration of free glutamic acid in brain is higher than in any other organ analyzed (muscle, liver, kidney, blood) After intravenous injection of large amounts of glutamic acid or of glutamine into rats and mice no increase in the glutamic acid content of the brain was found while the entrance of glutamine into the brain could not be excluded with certainty Glutamine appears to enter the liver with greater ease than does the parent amino acid The data suggest that brain glutamic acid may be derived from glucose through the tricarboxylic acid cycle At present, however, the possibility still exists that this amino acid originates at least in part from circulating glutamine The function of the system glutamic acid-glutamine is discussed as one of the metabolic buffers of the tricarboxylic acid cycle Under physiological conditions the large concentration of glutamic acid in the brain assures an optimal functional rate of the cycle at the ketoglutaric acid step Glutamic acid may furthermore act as a respiratory substrate under conditions of impaired glucose supply

Influence of lipotropic compounds on the lipid and protein fractions of blood plasma from children with nephrotic syndrome CHI CHE WANG, H H BOYLE and S FREEMAN *Children's Memorial Hospital & Northwestern Univ Medical School, Chicago, Ill* A total of 11 children with nephrotic syndrome and lipemia were treated during varying periods with one or more of the following compounds Methionine, inositol, choline In some cases an effect was demonstrated in the blood lipid values In one case all fractions but phospholipids

definitely decreased following the ingestion of 3 gm of inositol for 11 weeks and 5 days On the other hand 4 of the 5 patients receiving inositol alone showed no consistency in the lipid values during inositol intake One out of 5 patients showed a definite decrease in lipid values during the administration of choline alone Two children who received a combination of 3 gm of inositol and 2 gm of choline for 9 days in the case of one patient and for 14 weeks 4 days in another patient showed a definite lowering of all the lipid fractions Four out of 5 children receiving 5 gm of methionine showed a lowering of the lipid fractions with some fluctuations In the fifth child there was a slight increase in neutral fat The lipotropic compounds did not produce a definite change in the protein fractions of blood plasma of these patients

Determination of pyrimidines by the isotope derivative method ROBERT C WARNER *Dept of Chemistry, New York Univ College of Medicine, New York City* Conditions have been established for the formation of derivatives of uracil and thymine with pipsyl (para-iodo-phenyl sulfonyl) chloride The reaction proceeds at room temperature in 75% acetone solution buffered with bicarbonate to give a 94% yield of the mono pipsyl ester With I^{131} in the derivatizing reagent, this reaction has been made the basis of a quantitative determination of uracil and thymine by the same method that has been applied to amino acids by Keston, Udenfriend and Cannan (*J Am Chem Soc*, in press) The pyrimidine solution is derivatized with isotopic reagent of known specific activity A large excess of the unlabelled derivative of the desired constituent is added as carrier A sample is purified to constant specific activity from which the quantity of the constituent originally present may be calculated Purification is accomplished by means of repeated recrystallization with nortite treatment and countercurrent distribution The latter method makes it possible to analyze for both uracil and thymine on the same reaction mixture after adding carriers for both Recoveries from mixtures and nucleic acid hydrolysates indicate an overall accuracy of 1-2% on quantities of 10 μ g Cytosine can be determined after conversion to uracil Data on the pyrimidine content and rate of hydrolysis of nucleic acids have been obtained by this method The indicator technique (Keston, Udenfriend and Levy *J Am Chem Soc* 69 3151, 1941) using both isotopes I^{131} and S^{35} and employing paper strip chromatography can also be applied to 0.1 μ g quantities of pyrimidine

In vitro metabolism of testosterone and its metabolites by kidney tissue CHARLES DONALD WEST (by invitation) and LEO T SAMUELS *Dept of Biochemistry, Univ of Utah, Salt Lake City, Utah* This investigation was undertaken to determine whether or not the kidney is involved in the

metabolism of testosterone When testosterone was incubated with dog or rabbit kidney mince, the testosterone was destroyed enzymatically and 17-ketosteroids were formed This destruction was accomplished by at least two enzyme systems One has DPN for its coenzyme and is concerned in the oxidation of the hydroxyl group on C-17 to the ketone The other enzyme system is much less active and is concerned in the saturation of the α - β unsaturated bond in the A ring When androstenedione was incubated with rabbit kidney mince, the 17-ketone group was destroyed while the α - β unsaturation in the A ring was left intact The addition of citrate greatly accelerated this reaction Similarly, the 17-ketone group of androsterone was destroyed when it was incubated with rabbit kidney mince This destruction was also catalyzed by the addition of citrate No α - β unsaturated steroids were formed from the androsterone The relation of these enzymes to those in the liver will be discussed

Dietary effects on liver xanthine oxidase W W WESTERFELD and DAN A RICHERT (by invitation) *Dept of Biochemistry, Syracuse Univ College of Medicine, Syracuse, N Y* Rats were born without detectable liver xanthine oxidase activity At 21 days of age the average activity was 720 units (Cmm O_2 /gm dry liver/hr) Adult rats on dog chow averaged 1550 μ Weanling rats were brought to 1535 and 1385 μ respectively by feeding dog chow (21% protein) or mineralized whole milk for 2 weeks Feeding purified diets containing 21% protein (casein, egg albumin, peanut protein) maintained the liver xanthine oxidase activity at approximately the weanling level (600-900 μ) for about 6 weeks, but gave values of 1000 to 1200 μ in 8 to 10 weeks Increasing the protein content of the diet to 25 and 30% by the addition of peanut meal gave only 900 to 1000 μ of liver xanthine oxidase after 6 weeks Supplementing the 21% purified casein diet with 10% dry liver gave 1290 μ of activity in 2 weeks, supplementing the diet with raw cream was similarly effective with some samples of cream but not with all A diet containing 21% crude casein gave 1260 μ of activity in 4 weeks Supplementing the purified casein diet for 2 weeks with a mixture of Cu, Zn, Mn, Co, and I or with a mixture of flavine, adenine, and ribose or with a mixture of biotin, inositol, p-aminobenzoic acid, pteroylglutamic acid, rutin and ergostanyl acetate did not significantly increase the liver xanthine oxidase above the control levels A concentrate of vitamin B_{12} was also ineffective

Progesterone and testosterone reversal of diethylstilbestrol inhibition of succinoxidase of tumor mitochondrial elements KENT WIGHT (by invitation) and DEAN BURK *National Cancer Institute, National Institutes of Health, Bethesda, Md* It has been found that certain hormones act

competitively on the succinoxidase system of the mitochondrial elements of the S91 and Harding-Passey melanomas grown in dba and C mice respectively The mitochondrial elements (microscopically visible cytoplasmic particulates mostly melanized, see Woods *et al J Nat Cancer Inst* Feb 1949) were obtained by centrifugation at 10°C of saline, glass wool-filtered tumor homogenates at 10,000 g for 30 minutes, after preliminary centrifugation at 25 g for 10 minutes to eliminate nuclei and heavy phagocytized cell material Oxygen consumption was measured manometrically after addition of 0.05M phosphate (pH 7), 0.00001M cytochrome C, and 0.02M succinate Diethylstilbestrol, at a concentration of $\sim 135 \gamma/\text{ml}$ ($\approx 0.0005M$), inhibited particulate oxygen consumption 60 to 75% This inhibition was markedly reduced or entirely eliminated by the simultaneous addition of $\sim 125 \gamma/\text{ml}$ ($\approx 0.0002M$) progesterone or testosterone Progesterone alone had no effect on oxygen consumption The S91 and Harding-Passey tumor particulates behaved similarly except that the normal QO_2 values ($\text{ml}^3 O_2$ consumed/mg/dry wt/hour) were about 5 times as great in the case of the former (QO_2 of 10-20 compared to 2-5), and that testosterone alone sometimes inhibited the latter Essentially no succinoxidase activity was shown by the initial nuclei fractions or the final supernatants Diethylstilbestrol also markedly inhibited or eliminated oxygen consumption by mitochondrial elements from non-melanoma tumors such as C3HBA breast carcinoma and sarcoma 37 grown in C3H and C mice respectively The foregoing observations on sex hormone antagonisms at the mitochondrial enzyme level may offer some basis of mechanism for the numerous similar antagonisms noted at organ and body levels

Paper chromatography of vitamin B_{12} and related bacterial growth factors WALTER A WINSTEN and EDWARD EIGEN (introduced by PHILIP B HAWK) *Food Research Laboratories, Inc, Long Island City, N Y* In a preliminary note (letter to the *Journal of Biological Chemistry*), *Lactobacillus leichmannii* 313 has been reported to utilize six alternate growth factors Two of these were found in vitamin B_{12} concentrates and presumably represent two forms of the vitamin Hoffmann, *et al (J Biol Chem* 176 1465, 1948) previously reported that crystalline APA factor (vitamin B_{12}) supports the growth of this organism A third growth factor may be identified as thymidine, reported by Snell, *et al (J Biol Chem* 175 474, 1948) to support the growth of *L leichmannii* 313 The three other growth factors are of unknown composition In the present report, the paper chromatographic procedure for separating the 6 alternate growth factors is described as well as the method of recognizing the positions of the several growth factors on a chromatogram by the use of *L leichmannii* 313 as

a microbiological indicator. This technique allows one to interpret assay values for apparent vitamin B₁₂ activity as measured in the tube microbiological assay procedure. Due to the very slow movement of the two forms of vitamin B₁₂ on a paper chromatogram using n-butanol as the mobile phase, it is possible to separate these entities from the faster moving substitute growth factors. The isolated vitamin B₁₂ entities may then be assayed by the usual tube assay procedure. Illustrative data are presented.

Metabolism of tissue cultures of mouse-brain in relation to propagation of Theiler's GD VII virus

RICHARD J. WINZLER and HAROLD E. PEARSON (by invitation) *Depts. of Biochemistry and Bacteriology, Univ. of Southern California School of Medicine and the Laboratory Division of the Los Angeles County Hospital, Los Angeles, Calif.* Sterile cultures of minced newborn mouse brain incubated at 35°C are capable of supporting the multiplication of Theiler's GD VII strain of mouse encephalomyelitis virus. Studies on the oxygen consumption in Warburg vessels of such cultures with or without virus reveal no significant difference in the QO₂ values in the presence or absence of the virus over the period of most rapid virus growth (0-24 hours) and up to 72 hours. Similarly with cultures grown in Erlenmeyer flasks the presence or absence of virus had no influence on the rate of glucose utilization or of lactic acid production by the tissues. The rates of oxygen consumption, glucose utilization and lactic acid production fall rapidly with time and reach levels of about 10% of the original rates after 48 hours. In spite of this marked diminution of metabolism, the tissue retains its ability to support the growth of the virus for as long as 10 days of incubation before virus is added. It thus appears that the virus has little effect on the overall metabolism of the host tissue and that the rate of metabolism of the host tissue is not of paramount significance in governing the multiplication of the virus.

Acetoacetate production from hexanoic and other six carbon acids by rat liver preparations

ROBERT F. WITTER (by invitation) and ELMER STOTZ *Dept. of Biochemistry, School of Medicine and Dentistry, The Univ. of Rochester, Rochester, N. Y.* Quantitative measurements of acetoacetate production from 6 carbon acids were made with rat liver homogenates and washed liver particulate matter. With the latter at pH 7.4-8.0, 1 mole of hexanoate yielded 1½ moles of acetoacetate, proving a recondensation mechanism. At pH 6-7 lower yields of acetoacetate were obtained at a slower rate, and a heat stable factor from liver was necessary. The rate of acetoacetate formation from several possible intermediates of hexanoate oxidation was measured with both types of liver preparations at pH 8.0. Only α-hexanoate yielded acetoacetate

at a rate comparable with hexanoate under the same conditions. In the washed liver system, sorbate, β-hydroxyhexanoate, β-hydroxy-γ-hexanoate, and β-ketohexanoate gave low rates of acetoacetate production. Upon addition of the heat stable factor, these rates were all increased but only with sorbate did the rate approach that of hexanoate or α-hexanoate. The washed liver system, unlike the homogenate or the soluble extract (Witter and Stotz *J. Biol. Chem.* 176: 501, 1948), did not metabolize triacetic (β,δ-diketohexanoic) acid. By use of a micro-bromination procedure for α-hexanoate, it has been found that its disappearance in liver homogenates is dependent on the presence of oxygen. Aerobically, β-hydroxyhexanoate did not inhibit the metabolism of α-hexanoate. The collected facts cast some doubt on a simple hydration of α-hexanoate and on β-hydroxyhexanoate as an intermediate. A study of various inhibitors is being made in an attempt to differentiate the steps in the production of acetoacetate from hexanoic acid.

Sulfur-free protein hydrolysates for cystine-

and methionine-free diets JOHN L. WOOD, SHIRLEY LUCILLE COOLEY (by invitation) and NELSON KINGSLAND (by invitation) *Dept. of Chemistry, School of Biological Sciences, Univ. of Tennessee, Memphis, Tenn.*

In order to prepare a diet entirely devoid of organic sulfur, excepting for vitamins, a method for removal of all sulfur from protein hydrolysates has been devised. The protein hydrolysates were treated with freshly prepared Raney Nickel which removed all organic sulfur as nickel sulfide. Model experiments indicate that the cystine in the mixture was converted to alanine and the methionine to α-aminobutyric acid. A 15% solution of the hydrolysate was shaken with Raney Nickel for 3 hours at room temperature and pH 8.2. The solution was separated from the nickel and neutralized before concentration to dryness. The nickel adsorbed considerable of the nitrogenous products of the solution, but much of this was eluted by treatment with hydrogen sulfide. The ratio of amino nitrogen to total nitrogen in the final product was approximately the same as in the untreated hydrolysate. Qualitative tests for cystine and methionine and sulfhydryl were negative. Threonine analyses indicated that this amino acid was not destroyed by the alkaline treatment. A small amount of sulfate was found in the hydrolysate. In one instance this was removed with barium hydroxide to produce an entirely sulfur-free hydrolysate. Growth response in young rats demonstrated that essential amino acids other than methionine were retained in the desulfurized preparation. Both an acid hydrolysate and an enzyme hydrolysate have been desulfurized. When supplemented with methionine, or with cystine and methionine, each preparation supported

growth at approximately the same rate as the untreated hydrolysate

Prolongation of pentobarbital sodium anesthesia by nitrates and nitrites HAROLD WOOSTER (by invitation) and F WILLIAM SUNDERMAN *Mellon Institute, Pittsburgh, Penna., and Cleveland Clinic, Cleveland, Ohio* The recovery time of white mice anesthetized with pentobarbital sodium is significantly prolonged by the intraperitoneal injection of nitroglycerine, butyl nitrate, diethyleneglycol dinitrate and sodium nitrite Nitroglycerine appears to be the most effective of the compounds studied The dosages required to demonstrate this phenomenon are of the order of 20-50 mg/kg of body weight Significant prolongation of recovery time may also be produced by the inhalation for 20 minutes of butyl nitrate in concentrations of 30-45 mg/l

Interference of gentisic acid in determination of urinary uric acid after administration of salicylates T F YÜ (by invitation) and ALEXANDER B GUTMAN *Research Service, First (Columbia Univ) Division, Goldwater Memorial Hospital, and Dept of Medicine, College of Physicians and Surgeons, Columbia Univ, New York City* The chromogen removed by treatment of urine or serum with uricase is generally considered to be true uric acid We find that in the urine of normal and gouty subjects receiving 5 gm acetylsalicylic acid daily, as much as 25% of the total chromogens (as measured by urea-cyanide-carbonate and arsenophosphotungstic acid) may consist of a chromogen which is not uric acid but is destroyed by digestion with uricase, due to instability in the alkaline buffer This chromogen was identified by counter-current techniques as largely gentisic acid, showing essentially the same distribution between dilute HCl and a mixture of isopropyl ether and petroleum ether as an authentic sample of gentisic acid When 16 gm of sodium gentisate was fed by mouth, the chromogenicity of the urine was tremendously increased, of this over 90% was gentisic acid In determining uric acid in the urine of patients receiving salicylates, gentisic acid should first be removed This can be accomplished by shaking an aliquot of acidified urine (pH 4.5-5.0) 2 or 3 times with 4 to 5 times the volume of ethyl ether The gentisic acid is quantitatively removed in the ether extract

Metabolism of isovaleric acid studied with isotopic carbon IRVING ZABIN (by invitation) and KONRAD BLOCH *Dept of Biochemistry and Institute of Radiobiology and Biophysics, Univ of Chicago, Chicago, Ill* In continuation of earlier studies on the degradation of branched chain compounds and their possible role in sterol synthesis (*J Biol Chem* 155 255, 1944), isovaleric acid containing C^{13} in the two end methyl groups and C^{14} in the carboxyl group has been synthesized

After incubation of labeled isovaleric acid in rat liver slices ketone bodies were isolated according to Van Slyke and analyzed for C^{13} and C^{14} The acetone fraction which includes acetone formed by decarboxylation of acetoacetate contained the C^{13} and C^{14} isotopes in a ratio of about 8 to 1 Two possible pathways for the formation of ketone bodies from isovaleric acid are a) loss of one of the end methyl groups with formation of a 4 carbon acid followed by oxidation of the latter to acetoacetate, b) oxidation of isovaleric acid at the tertiary carbon atom with production of acetone and a 2 carbon fragment The 2 carbon fragment might condense to acetoacetate The high absolute C^{13} concentration and the high C^{13}/C^{14} ratio found in the acetone fraction in the present experiment favors a pathway which involves splitting of isovaleric acid into three carbon and two carbon fragments Cholesterol isolated from the same incubation experiment contained both carbon isotopes, the incorporation of C^{13} being significantly greater than that of C^{14}

Distribution of radioisotopes of carbon and calcium administered to rats by continuous intraperitoneal infusion S H ZBARSKY (by invitation), ROGER LIENKE (by invitation) and W D ARMSTRONG *Dept of Physiological Chemistry, Univ of Minnesota Medical School, Minneapolis, Minn* Studies were made of tissue uptake and excretion of C^{14} and Ca^{45} by rats receiving these isotopes by intraperitoneal infusion The C^{14} was given as a solution of $Na_2C^{14}O_3$ in saline and the C^{14} in the expired air and excreta determined at intervals over a period of 5 days The C^{14} content of the expired air rapidly reached a high value which was maintained throughout the injection Over 90% of the injected C^{14} was excreted in the expired air and the C^{14} contained in the urine was present chiefly as urea The specific activities of the tissues and tissue components were found to be higher than in earlier experiments in which rats received intermittent injections of $Na_2C^{14}O_3$ or intraperitoneal implants of $CaC^{14}O_2$ The Ca^{45} was given over a period of 3 days as a solution of $Ca^{45}Cl_2$ in saline Feces and urine were collected daily during this time and for 5 days after the infusion was stopped, Ca^{45} appeared in all samples of feces and the total fecal excretion of Ca^{45} was nearly equal to the amount in the urine The Ca^{45} present in the skeleton, teeth and other tissues was determined The results and conclusions derived from these and other similar experiments will be presented

Effect of antimalarial agents on adenosine triphosphatase of snake venoms E ALBERT ZELLER (introduced by MARSCHELLE H POWER) *Division of Biochemistry, Mayo Foundation, Rochester, Minn* Many snake venoms are able to catalyze the hydrolysis of one phosphoric acid from ATP

This reaction is activated by some bivalent ions like magnesium, calcium, manganese and cobalt, and is inactivated by some other ions such as zinc, copper and mercury (E A Zeller, 1948) Hydrogen sulfide, cysteine and ascorbic acid inhibit the reaction while sodium cyanide activates it, possibly by removing inhibiting heavy metals Histamine inactivates the enzyme considerably in 0.001M solutions Other diamines, like pyridoxamine, have the same effect (E A Zeller *Proc Soc Exper Biol & Med*, 1949) It has been observed recently that still other drugs which are derivatives of diamines also influence ATPase in a similar way Thus, stilbamidine in 0.004M solution produces 63% inhibition of ATPase from *Butis gabonica*, regardless of the degree of activation of the enzyme by magnesium ions An approximately similar degree of inhibition of this enzyme is also produced by 0.003M quinine and 0.0015M atabrine in the presence of various concentrations of magnesium ion It is of interest to note that dephosphorylation of ATP by homogenates of guinea-pig adrenal glands was likewise inhibited to a similar extent by stilbamidine and atabrine

Non-choline esters as substrates of e-cholinesterase ('true' cholinesterase) E ALBERT ZELLER, GERARD A FLEISHER and ROBERT A McNAUGHTON (introduced by MARSCHELLE H POWER) *Division of Biochemistry, Mayo Foundation, Rochester, Minn* It has been shown that cholinesterase, which is present in certain snake venoms, is of the 'e' type (Zeller *Helvet chim acta* 33 1949) and that it is able to hydrolyze ethyl haloacetates (Zeller and Utz, *Helvet chim acta* 33 1949) The same result has been obtained with ethyl chloro acetate and e-cholinesterase of human erythrocytes (McNaughton and Zeller *Proc Soc Exper Biol & Med*, 1949) The use of the above-mentioned esters has two disadvantages 1) the enzymatic reaction is rather slow as compared to that obtained with acetylcholine and 2) the substrate blanks are relatively high We looked, therefore, for better non-choline substrates of cholinesterase β -Chlorethyl acetate was hydrolyzed by different snake venoms (*Naja naja*, *Naja melanoleuca* and *Pseudechis porphyriacus*), and erythrocyte cholinesterase at a suitable rate The non-enzymatic blanks were much lower than those of the other substrates Enzymatic hydrolysis of this compound and of acetylcholine was inhibited to the same degree by physostigmine Simultaneous hydrolysis with different concentrations of this non-choline ester and acetylcholine always resulted in competitive inhibition, both with hemolyzed erythrocytes and with snake venom Purified cholinesterase from human erythrocytes (which, contrary to the unpurified hemolyzed erythrocytes, does not split methyl butyrate) also catalyzed the hydrolysis of β -chloroethyl acetate, and gave rise

to competition with acetylcholine The β -Chloroethyl acetate was split more quickly by e-cholinesterases (snake venoms, erythrocytes) than by s-cholinesterases ('pseudo-' cholinesterase) from human serum or guinea-pig parotid glands

Effect of ultrasonic vibrations on the release and inactivation of paramycin L P ZILL (by invitation) and W J VAN WAGTENDONK *Dept of Zoology, Indiana Univ, Bloomington, Ind* Experiments were carried out to determine the feasibility of using high frequency ultrasonic vibrations as a method of disintegrating large numbers of *Paramecium aurelia* as a preliminary step in the isolation of paramycin ('killer' substance of *Paramecium aurelia* 51, variety 4) The instrument used had a maximum input of 1000 watts at a frequency of 450,000 cycles/sec Tests which were run on whole animals demonstrated that complete disintegration was not obtained with maximum input for five minutes Paramycin was completely inactivated during this treatment In order to investigate ultrasonic effects on paramycin itself, experiments were performed, using a brei prepared by repeatedly forcing a suspension of *Paramecium* through a narrow-gauge injection needle It was found that ultrasonic treatment at low intensity increased the activity of the original brei The maximum increase in activity was found to be obtained with a constant current of 80 milliamperes (ca 32 watts) and at a bath temperature not exceeding 6°C All further experiments were performed under identical conditions of vibration (constant current of 80 milliamperes) If vibration was carried out under an atmosphere of air or oxygen, increases in activity up to 185% were observed No increase or decrease in the apparent activity of the brei was found if the vibration took place under an atmosphere of nitrogen When oxygen was passed through the sample during vibration, the inactivation of paramycin proceeded according to a first order reaction

Polarographic micro-method for determination of chloride in whole blood, serum and plasma WALTER J ZIMMERMAN and WILLIAM M LAYTON, JR (introduced by H JENSEN) *Medical Department, Field Research Laboratory, Fort Knox, Ky* A polarographic method has been developed for the determination of chloride concentration in from 0.02 to 0.05 ml of whole blood, plasma and serum Proteins are removed by an adaptation of the Somogyi barium hydroxide-zinc sulfate precipitation, the final dilution of the sample for analysis being 1:100 in 0.1N potassium nitrate The diffusion current, determined by a manual polarograph at an applied voltage of 0.0 volts against a saturated mercurous sulfate half cell has been found to be directly proportional to chloride concentration in the range of concentration used It is unnecessary to calibrate the apparatus in absolute

units or to thermostat the analysis cell, provided the diffusion current is determined for two standard chloride solutions. The method has been tested for accuracy by means of duplicate determinations on 0.05 ml. of plasma with a mean error of 0.6% and by addition of 40 millimoles of potassium chloride with a mean error in recovery of 0.8%. Plasma chloride values obtained by the polaro-

graphic method have been found to correspond with values obtained with identical solutions by a standard volumetric technic. The polarographic method has the advantage of utilizing small volumes of blood, thus allowing frequent serial chloride determinations on small laboratory animals without causing undesirable changes attending excessive blood loss.

AMERICAN SOCIETY FOR PHARMACOLOGY AND EXPERIMENTAL THERAPEUTICS, INC.

Thirty-ninth Annual Meeting

DETROIT, MICHIGAN, April 18-22, 1949

(For possible corrections in any of the following abstracts see the June issue)

In vitro oxidation of morphine by tissue homogenates L G ABOOD and ERNEST KUN (introduced by JULIUS M COON) *Dept of Pharmacology, Univ of Chicago, Chicago, Ill* Isotonic tissue homogenates prepared in Krebs-Henseleit solution oxidize morphine *in vitro* Morphine derivatives in which the phenolic hydroxy group is substituted are not oxidized, but depress the endogenous oxygen uptake The oxidation of morphine sulfate was followed manometrically and colorimetrically by determining the reducing value of the flask contents In 1 hour 70 to 80% of the added morphine was oxidized, a fact which corresponds to an equivalent decrease in the reducing value of the reaction mixture (10-100 mg of tissue homogenate plus 10 mg of morphine sulfate), suggesting that the phenolic hydroxy group is oxidized probably to a quinone On this basis 1 mole of morphine utilizes one-half atom of oxygen, which is in agreement with the experimental findings The oxidized morphine is still pharmacologically active, and it is not further oxidized by tissue preparations Muscle, brain, liver, kidney of rabbit, rat, and guinea pig were all able to oxidize morphine Invertebrate tissues also oxidize morphine The extra oxygen consumption of 10 mg of morphine is depressed 59% by 0.01M NaCN, 83% by 0.01M Na-ScO₂, while no inhibition occurred with 0.01M NaN₃ or 0.001M HgCl₂

Effect of morphine sulfate on cerebral blood flow and metabolism in man BENEDICT E ABREU, HENRY W ELLIOTT, VIOLETTE C SUTHERLAND (by invitation), LESTER MARGOLIS (by invitation) and ALEXANDER SIMON (by invitation) *Divisions of Pharmacology and Experimental Therapeutics and of Psychiatry, Univ of California Medical School, San Francisco, and Langley Porter Clinic, State Dept of Mental Hygiene, San Francisco, Calif* Mean arterial blood pressure (MBP), cerebral blood flow (CBF), cerebral O₂ and glucose uptake and CO₂ output were determined in 5 subjects before and 20 minutes after morphine SO₄, 10 mg, 1 m All were voluntary patients who were in the Langley Porter Clinic for psychiatric care Results expressed as percentage change from the control values are indicated in the table

Pt	Sex	M B P	C B F	O ₂	CO ₂	Glucose
M R	f	-7	-21	-32	-19	0
M P	f	+9	-22	-31	-25	-19
R R	m	+3	-3	+4	-2	+124
S M	m	0	-9	-17	-26	+40
J T	m	+3	+58	+60	+47	+124

The trend of effect as indicated in 5 subjects is for morphine to decrease significantly the CBF (in 2 of 5), O₂ uptake (in 3 of 5), CO output (in 3 of 5), but to increase glucose uptake (in 3 of 5)

Simple method for determining the degree of vascular sympatholytic action RAYMOND P AHLQUIST *Dept of Pharmacology, Univ of Georgia School of Medicine, Augusta, Ga* The increasing use of sympatholytic agents as tools in pharmacological and physiological research has demonstrated the need for a simple method for determining more exactly the degree or extent of sympatholysis present in the experimental animal The proposed method is based on the reduction, by sympatholysis, of the intense vasoconstriction produced by the injection of epinephrine, 0.005 mg/kg, into the femoral artery This dose, which practically always produces a marked pressor response when injected intravenously, has little or no pressor effect when injected into the femoral artery of untreated dogs As sympatholysis develops following the administration of Dibenamine, Priscol or other sympatholytics, this intraarterial constricting effect becomes diminished, and the pressure response to the intra arterial injection becomes more similar to the intravenous response This method gives much more information regarding degree of sympatholysis than does a determination of the presence or absence of epinephrine 'reversal' This is well illustrated by the finding that even though epinephrine 'reversal' is present, the intra arterial injection shows that epinephrine is still capable of producing marked vasoconstriction It has also been found that in some of the visceral vascular beds the vasoconstricting action of epinephrine cannot be prevented by any dose of the sympatholytic agents tested thus far

Sympatholytic action of dibenamine RAYMOND P AHLQUIST *Dept of Pharmacology, Univ of Georgia School of Medicine, Augusta, Ga* Nickerson

et al first showed that epinephrine, even in very high dosage, produced only a depressor response when injected intravenously into cats or dogs following an effective dose of Dibenamine. Although this tends to show that the sympatholytic action of Dibenamine is absolute against epinephrine constriction, results obtained in this laboratory, using direct blood flow measurements and intra-arterial injections of epinephrine, show that the action of Dibenamine is not absolute. Epinephrine continued to produce constriction in the vascular bed of the pregnant dog's uterus following doses of Dibenamine up to 40 mg/kg. In these same experiments the epinephrine also produced uterine contractions after Dibenamine. In some dogs it was found that the femoral intra-arterial injection of epinephrine continued to produce vasoconstriction following high doses of Dibenamine although the usual response in this case is a slight vasodilation. Other vascular beds are still under investigation. These results emphasize the fact that the response to epinephrine following sympatholytic agents is determined by the ratio between the receptors which respond unchanged to epinephrine (vasodilation, uterine inhibition etc.) and the receptors whose response is decreased but apparently not completely abolished (vasoconstriction, uterine stimulation, etc.). These results also indicate that the apparent differences between so-called 'adrenolytic' and 'sympatholytic' action are probably not real since intra-arterial injection of epinephrine corresponds more closely to sympathetic nerve stimulation (other than to the adrenal medulla) than does intravenous injection.

Influence of orally administered rutin on adrenal ascorbic acid storage in guinea pigs. ANTHONY M. AMBROSE and FLOYD DEEDS. *Pharmacology Laboratory, Bureau of Agricultural and Industrial Chemistry, Agricultural Research Administration, USDA, Albany, Calif.* In a previous paper we have shown that guinea pigs maintained on a scorbutogenic diet and receiving suboptimal doses of ascorbic acid (0.2 mg/day) in conjunction with rutin (100 mg/day) survived longer and showed less severe scorbutic symptoms than guinea pigs receiving ascorbic acid or rutin alone. In the light of results by Cotureau *et al* (*Nature* 161: 557, 1948) on the 'sparing action' of vitamin P or catechin on adrenal ascorbic acid, it was felt that this approach to the evaluation of the physiological role of rutin might be more objective. Accordingly, 120 young guinea pigs were divided into 4 groups of 30 each and placed on a scorbutogenic diet. In addition the following supplements were administered orally each day. One group served as control, one group received 100 mg rutin in 0.25 ml propylene glycol, one group received 2 mg ascorbic acid, and another group received 2 mg ascorbic acid and 100 mg rutin. After 12 to 20 days, 8 animals from each

group were sacrificed and adrenal ascorbic acid determined by the method of Roe and Kuether. Our results indicate that rutin appears to play no important role as an 'economizing factor' in the storage of adrenal ascorbic acid under the conditions of our experiments. Smaller doses of ascorbic acid, 1 mg or 0.5 mg/day, clearly demonstrate that as the dose of ascorbic acid is lowered there is an accompanying lowering of the amount of adrenal ascorbic acid stored irrespective of rutin.

Aureomycin protective effect in experimental Rocky Mountain spotted fever with particular reference to intermittent treatment. LUDWIG ANIGSTEIN, DOROTHY M. WHITNEY, and JOE BENINSON (introduced by G. A. EMERSON). *Rickettsial Research Laboratory, Dept of Preventive Medicine and Public Health, Univ of Texas Medical Branch, Galveston, Texas.* Time-dose relationships in intermittent aureomycin therapy of spotted fever is the subject of this study. A total of 30 guinea pigs were infected with spotted fever and subsequently injected subcutaneously with repeated single doses of 10, 20, and 30 mg of aureomycin hydrochloride (Lederle) per guinea pig (weighing 450-500 gm), at 48- and 72-hour intervals. Four injections were given to each test animal covering the incubation and most of the febrile period of the controls. A drastic change of the clinical pattern of the infection was manifested by all treated guinea pigs. The fever was either entirely suppressed or reduced to abortive attacks after long incubation, regardless of time-dose schedule. Whereas the untreated controls developed typical spotted fever and died, all test animals recovered with immunity to reinoculation with spotted fever. Evidence was thus gained that intermittent aureomycin therapy with minimum dosage is equally efficient in spotted fever as the continuous massive treatment. The protective effect of aureomycin and the ultimate immunity of the infected guinea pig express the balance kept by the antibiotic between the rickettsial invader and the host resistance. This was substantiated by the specific antibody response in the mechanism of the rickettsiostatic activity of the antibiotic as found by complement fixation tests. This phase of the problem is under study.

Physiological disposition of aminopyrine in man. JULIUS AXELROD (by invitation) and BERNARD B. BRODIE. *Dept of Biochemistry, New York Univ College of Medicine, New York Univ Research Service, Goldwater Memorial Hospital, and Laboratory of Industrial Hygiene, New York City.* Aminopyrine is quickly and essentially completely absorbed from the gastro-intestinal tract. Only about 2% of the drug is excreted unchanged indicating its almost complete metabolism in the body. Plasma levels decline slowly, about 15 to 20% per hr. The route of metabolism of amino

pyrine was shown to be as follows. About 55% of the drug demethylates to form 4-aminopyrine, which in turn is acetylated and excreted in this form. The other route or routes of metabolism were not ascertained. Preliminary results suggest that 4-aminoantipyrine is an effective antipyretic, antirheumatic and analgesic.

Differentiation of sympathetic from parasympathetic drugs by measurements of phaseboundary potentials. T. C. BARNES and R. BEUTNER, *Hahnemann Medical College and Hospital of Philadelphia, Philadelphia, Pa.* The oil-cell method (Barnes and Beutner, *Science* 104: 569, 1946) provides a basis for the distinction between adrenergic and cholinergic nerves. Previous reports (*Federation Proc.* 4: 112, 1945; *Internat. Physiol. Congress* 1947, p. 60) showed that adrenergic drugs dissolve in triglyceride oils on which they form negative phaseboundary potentials. In contrast, the cholinergic drugs, choline, acetylcholine, mechoyl, pilocarpine, eserine, prostigmine, etc. are inactive on adrenergic oils. Tests show that atropine, curare and etamon also have the solubility of cholinergic drugs. The alipathic sympathomimetics give potentials with the adrenergic oils. (In this abstract all concentrations are 0.05% and potentials negative.) Aranthol gave 19 mv. on tributyrin, octin produced 32 mv. on triacetin and octethyl gave 15 mv. on triacetin. Adrenergic blockade may be competitive negativity since priscol produced 45 mv. on tributyrin, yohimbine 77 mv. on tributyrin and dibenamine 6 mv. on triacetin. Most ergot compounds are difficult to test in the oil cell but ergonovine gave 53 mv. on the adrenergic oil tributyrin. It is interesting that nicotine has the solubility characteristics of adrenergic drugs giving 87 mv. on tributyrin suggesting that the pressor effect is direct adrenergic action. The problem of nicotinic and muscarinic effects is now being investigated by the oil cell method.

Relation of 4-methyl and 4-ethyl substituted imidazoles to 1) histaminic action, 2) antagonism by antihistaminics. W. BARRETT (by invitation), J. FEICKERT (by invitation), B. CRAVER, *Division of Microbiology, Research Dept., Ciba Pharmaceutical Products, Inc., Summit, N. J.* In respect to the relation between chemical structure and histaminic activity as judged by the stimulating action of these compounds upon the smooth muscle of the ileum of the guinea pig, the following observations seem justifiable. The activity appeared progressively to diminish as one or both of the hydrogens of the amino group were replaced by alkyl groups, and the length of these alkyl groups was extended, the replacement of the amino group with other groups diminished or eliminated the activity, the amino methyl derivative of imidazole was devoid of this action unless at least one hydrogen were substituted by an alkyl group,

but otherwise the effect of increasing the length of the alkyl group was the same as in the ethyl series. As to the relation between the chemical structure of these compounds and the antihistaminic activity of Pyribenzamine, the following conclusions appear justifiable. Minimal doses eliminated the histaminic action of the compound in the ethyl series only in the presence of an amino group, whether it were mono- or di-substituted, but in the methyl series the low doses of Pyribenzamine sufficed only if but one hydrogen had been replaced by an alkyl group and not if both had been replaced. Its antagonism in high doses toward other derivatives would appear attributable to its mild anticholinergic activity.

Effect of certain mitotic poisons on uric acid and allantoin excretion in mice. ALLAN D. BASS and ELIZABETH F. PLACL, *Dept. of Pharmacology, College of Medicine, Syracuse, N. Y.* KOPAC (*Tr. N. Y. Acad. Sci.* 8: 5, 1945) has called attention to the relationship of mitotic poisons to nucleoprotein systems. Krizik *et al.* (*U. S. Atomic Energy Commission Report* MDCC 1647) found no increase in uric acid or allantoin in the urine of dogs given lethal doses of X-ray, a well established mitotic inhibitor. These observations appeared to be somewhat at variance in light of the reduction in amount of lymphoid tissue we have observed in mice following administration of such mitotic poisons as nitrogen mustard and urethane. A study was therefore begun to determine in mice the effect of mitotic poisons on the products of nucleoprotein catabolism. C3H or C3H₁ hybrid mice bearing 6C3H1ED tumors were used since these lymphoid tumors gave a large reservoir of lymphoid tissue high in nucleoproteins. Urine was collected from groups of 10 to 15 animals over a period of three hours. Daily doses of colchicine (0.75 mg/kg) and nitrogen mustard (2 or 4 mg/kg) in saline were administered intraperitoneally. Uric acid-creatinine and allantoin-creatinine ratios were determined since only fractions of the 24-hr. output of urine were collected. The uric acid-creatinine ratio was elevated in the 6 to 48 hour period following drug administration. The allantoin-creatinine ratio was elevated to a lesser extent. Less striking but definite changes were observed in non-tumor bearing animals. Blood uric acid levels were also found to be elevated following administration of the agents used. The findings suggest that no major defect in nucleoprotein catabolism is affected by the mitotic poisons studied.

The subcutaneous use of thimerin, a new mercurial diuretic for treatment of congestive heart failure. ROBERT C. BATTERMAN, DAVID UNTERMAN (by invitation) and ARTHUR C. DEGRAFF, *Dept. of Therapeutics, New York Univ. College of Medicine, New York City.* The diuretic effectiveness in terms of predictability of

response, and degree of diuresis was ascertained for a new mercurial diuretic, Thiomerin, N(β -carboxymethyl mercapto-mercuri- γ -methoxy) propyl camphoramic acid disodium salt. In a group of 45 patients with congestive heart failure, the subcutaneous administration of Thiomerin resulted in a satisfactory diuresis in 86.6% of trials as compared with 81.0 and 83.3% of the trials for Thiomerin and Mercuzanthin respectively, given intravenously. The degree of diuresis for each drug regardless of route of administration was equivalent, indicating that complete absorption occurred from the site of subcutaneous injection. In an additional group of 35 ambulatory and 73 bedridden patients, Thiomerin when administered subcutaneously was satisfactory in removing the edema, preventing the accumulation of edema and for maintenance of patients' state of compensation. In all 589 injections of 1 to 4 cc of Thiomerin were given subcutaneously to 143 hospital and ambulatory patients. The drug was well tolerated by the patients in 90% of the trials. Subjective burning at the site of injection occurred in approximately 10% of the number of injections. Tender induration and nodular formation was noted in 4 and 2.5% respectively. Thiomerin when given subcutaneously is an effective and safe diuretic with a predictability of diuretic response and degree of diuresis equivalent to that noted with other mercury diuretics used intravenously and is superior to these preparations used intramuscularly.

Subacute respiratory toxicity of a new insecticide activator in 'aerosol bomb' mixture. ROBERT O. BAUER and WALTER W. JETTER (introduced by GEORGE L. MAISON) *Dept of Pharmacology, Boston Univ School of Medicine, Boston, Mass.* Animals were exposed in a closed chamber to dispersions of insecticide mixtures in air 1 hour a day for 4 weeks. The mixture contained (activator) N-octyl bicycloheptene dicarboximide 2%, (insecticide) DDT 2% in kerosene) 1%, (vehicle) methylene chloride 5%, alkyl naphthalenes 5%, freons 11 and 12, 85%. Two concentrations at 1 gm and 0.1 gm/60 l air were used. Ten guinea pigs and 10 Wistar rats were subjected to each concentration. An equal number served as controls. Hemoglobin, red and white cell counts, urinary albumin and sugar were estimated before and after the experiment. The test animals displayed irregular food consumption. Group growth curves were depressed. Surviving test animals regained lost weight completely. Only 4 fatalities occurred and these were in rats on high concentrations. In both species fine tremors, hyperirritability and conjunctival hyperemia were observed, becoming progressively worse and disappearing after exposure. Female guinea pigs receiving high concentrations developed reversible alopecia. Mild anemia in test guinea pigs

and leucopenia in test rats were encountered irregularly. Incomplete pathologic examinations show 1) moderate to severe interstitial pneumonitis in all test animals, 2) focal necrosis of liver and spleen in high concentration rats, 3) extensive splenic hemosiderosis and hypoplastic bone marrow, chiefly in high concentration guinea pig group. Pneumonitis and conjunctival hyperemia in test animals point to direct chemical irritation, more likely due to the vehicle than the insecticide or activator. Other clinical and pathologic changes may result from the insecticide mixture, nutritional disturbance or a combination.

Survival of plasmodium cathemerium sporozoites in hen blood with addition of canary blood cells. HARRY BECKMAN *Marquette University School of Medicine, Milwaukee, Wis.* Mosquitoes carrying the sporozoites of *P. cathemerium* 3H2 were ground in Locke's solution and added simultaneously to freshly prepared hen plasma to which there had been added to respective portions a) freshly washed canary blood cells, b) freshly washed hen blood cells, c) a mixture of freshly washed canary and hen blood cells. The three mixtures were incubated with gentle agitation at 41.5° C for 1 hour and then portions representing 1 mosquito each were withdrawn and injected intramuscularly into canaries, the peripheral blood of these birds being subsequently examined from the 5th to 16th days, inclusive. Birds failing to become positive were challenged by mosquito bite. Trials employing 4 birds in each group were run at sufficient intervals that at least one complete 3-week sporozoite-to-sporozoite cycle lay between. Of the 16 canaries injected with hen plasma plus canary cells, all developed patent blood infections. Of the 16 injected with hen plasma plus hen cells, none developed patent infections and all became infected when later challenged by mosquito bite. Of the 16 birds injected with hen plasma plus both hen and canary cells, 13 developed patent blood infections. It would appear from this preliminary study that it is the formed elements of canary blood that permit survival of sporozoites in hen plasma, in which alone they do not survive, as earlier shown in this laboratory.

Some metabolic changes observed in seizures induced by certain agenetreated protein in dogs. JULIUS BELFORD (by invitation) and D. D. BONNycastle *Laboratory of Pharmacology, Yale Univ., New Haven, Conn.* The resemblance to human epilepsy of the motor seizure and EEG dysrhythmia occurring in canine 'epilepsy' (caused by certain 'agene' (NCl₃)-treated proteins such as wheat gluten and zein etc.), warranted further study of this seizure phenomena. Five to 8 dogs were employed in each experiment and were classified as being in the normal, pre-fit, fit, (and when feasible) inter-paroxysmal stage. Blood samples

were taken from these animals and examined for various entities. These results were subjected to statistical examination. No significant changes were found at these several stages in serum calcium, magnesium or choline esterase. The intravenous injection of 100 mg of physostigmine, reputed to lower serum choline esterase by 95% did not precipitate convulsions, on the other hand, sub-convulsive doses of metrazol could induce a seizure. No significant differences were found in arterial glucose, but a significant pre fit fall occurred in venous glucose followed by a rise during a seizure. No significant A-V glucose differences were observed although there was a tendency towards negative A-V differences in the abnormal phases. The oxygen content of arterial and venous blood showed no change. However, while the arterial carbon dioxide did not change, the venous carbon dioxide fell significantly at the time of the fit.

Observations on administration of BAL in selenium poisoning. J B BRIGORSKY (by invitation) and DONALD SLAUGHTER, *Dept of Physiology and Pharmacology, Univ of South Dakota School of Medicine, Vermillion, S D*. Braun, Lushy and Calvery, (*J Pharmacol & Exper Therap* 87: 119, 1946) reported that BAL was not only ineffective in the treatment of selenium poisoning but actually increased the toxicity of this element in experimental animals. Because of the prevalence of selenium in the soil of this region, further work seemed pertinent. Twenty young rats were used in each of three experiments, sodium selenite (SS) was administered intraperitoneally, BAL intramuscularly. Animals were injected daily for a period of 14 to 24 days. Varying doses of SS caused no toxic symptoms until a level of 10.0 mg/kg was reached. When a non-toxic dose of BAL (15.0 mg/kg) was administered $\frac{1}{2}$ hour following the injection of a nontoxic dose of SS, (5.0 mg/kg) all animals died. This would seem to indicate that BAL and SS have a synergistic toxicity. Durlacher *et al*, (*J Pharmacol & Exper Therap* 87: 28, 1946) state that BAL is toxic in a 15 mg/kg dose but our work does not bear out this statement. As a matter of fact, histological examination of the liver following BAL alone reveals no pathological changes. Since the liver is considered to be the probable site for detoxification of SS, it is of unusual interest to observe that BAL prevented the necrosis and fat deposits produced by SS alone. Further experimental work to elucidate this seeming paradox is being conducted.

Alteration of the activity of the human gastrointestinal tract with dihydroergocornine methanesulfonate (D H O 180). W D BENNETT (by invitation), L E MORRIS (by invitation) and O SIDNEY ORTH, *Depts of Anesthesiology and Pharmacology, Univ of Wisconsin Medical School, Madison, Wis*. Administration of the dihydroergot

derivatives, particularly dihydroergocornine methanesulfonate (D H O 180—Sandoz), may elicit initially unfavorable side effects such as anorexia, nausea and vomiting. When this drug was given to block possible cardiac irregularities before cyclopropane anesthesia, it was noted subsequently in patients in which laparotomies were performed that the intestines were quite contracted, in fact that they had a ribbon-like appearance. It seemed possible that such evident stimulation of the gastrointestinal tract could be used to advantage clinically if the proper amount of one of these relatively non-toxic dihydroergot compounds was used. Dihydroergocornine has been administered in doses of up to 4 mg total intravenously given in about 4 minutes, 1-2 mg as a single dose intramuscularly, or 3 mg q i d orally. In cases of intestinal distention, intestinal obstruction, and congenital megacolon, this drug has been found to be distinctly advantageous.

Paralysing action of 2-methyl, 2-n-amy-4-hydroxymethyl-1,3-dioxolane (glyketal). F M BERGER (introduced by ARNOLD D WELCH) *Univ of Rochester School of Medicine, Rochester, N Y*. Numerous 2 substituted-4-hydroxymethyl-1,3 dioxolanes possess central depressant properties similar to those of the glycerol ethers or benzimidazoles. 2-methyl, 2-n-amy-4-hydroxymethyl-1,3-dioxolane appeared most active in this respect. This compound in doses of 100-150 mg/kg injected intraperitoneally to small laboratory animals caused paralysis of the voluntary muscles. During paralysis respiration was not depressed and the animals remained conscious. There was a marked decrease of muscular tone. The muscles remained excitable to direct and indirect stimulation and there was no curare-like action. The corneal and pupillary reflexes and the knee jerk remained unaffected. The animals did not react to painful stimuli of moderate intensity. This was probably due to the motor paralysis. The compound had no analgesic action in nonparalytic doses. Paralysis was followed by complete recovery of all functions. After lethal doses death was due to respiratory paralysis. On intravenous injection mild and transient peripheral vasodilatation was caused. The action of acetylcholine was not interfered with. Glyketal also had a local anesthetic and quindine-like action. Its anticonvulsant action against strychnine was of a similar order as that of myanesin. Myanesin and glyketal differed in their metrazol antagonism. Myanesin had little effect on the occurrence of convulsions but protected the animals from death. Glyketal behaved as a true, although inefficient, anticonvulsant by protecting the animals from both convulsions and death.

Ratio of amino acid nitrogen to creatinine in the urine as a sensitive diagnostic test for ura-

num poisoning in the rabbit H BERKE AND A ROTHSTEIN (introduced by H C HODGE) *Dept of Radiation Biology, Univ of Rochester, Rochester, N Y* It has been shown in this laboratory that the ratio of amino acid nitrogen to creatinine in the urine was a sensitive indicator of uranium poisoning in the rabbit During daily exposure to inhalation of uranium dusts, the ratio remained elevated in contrast to the more or less rapid decline of other blood and urine constituents which also became abnormally high soon after exposure to uranium More detailed experiments, therefore, were set up to determine the animal response in terms of this ratio to intravenous administration of uranyl nitrate The minimal dose of uranyl nitrate which gave a statistically significant increase in ratio was 0.02 mg U/kg The ratio was a more sensitive test than either urinary protein or blood NPN Blood amino acid nitrogen remained normal in all animals, indicating that the amino aciduria was renal in origin Multiple injections of UO_2NO_3 at 2- to 3-week intervals at levels of 0.04, 0.1 and 0.2 mg U/kg showed 3 patterns of response as measured by the ratio In general the magnitude of the response was proportional to the dose given At lower levels of administration, the maximal increase in the ratio occurred soon after each injection of uranium followed by lower but still high values The peak values following each injection either remained the same, declined or increased in value depending on the dose given A few animals, observed for 3 months after their last multiple injection, still showed abnormally high values of the ratio, even though histological examination revealed no renal damage directly attributable to uranium

Effect of a number of aralkylamines on tyramine oxidation by amine oxidase FREDERICK BERNHEIM and EDWIN J FELLOWS *Duke Univ School of Medicine, Durham, N C and Temple Univ School of Medicine, Philadelphia, Pa* The present experiments were carried out in order to determine if a correlation existed between the central excitatory and amine oxidase inhibitory activity of a number of benzylamine, beta-aryl-ethylamine and aryl-2-aminopropane modifications In many instances an excellent correlation was observed, however, there were notable exceptions Injection of several 3-amino-1-phenylbutane and 4-amino-1-phenylpentane derivatives and subsequent histopathological examination of the brain and cord of these animals disclosed a destructive effect on certain cells of the nervous system Since enzymatic data on this type compound were not available, it appeared desirable to include them in the present studies All of these agents exhibited a significant amine oxidase inhibitory effect

Chemotherapeutic effect of 8-amino quinolines

in schistosoma mansoni infections in mice RAYMOND N BIETER, ELIZABETH M CRANSTON, WAYNE CHADBURN (by invitation), ASHTON C CUCKLER (by invitation), DOMINIC DEGIUSTI (by invitation), W W BECKLUND (by invitation), and HAROLD N WRIGHT *Dept of Pharmacology, Univ of Minnesota Medical School, Minneapolis, Minn* Two 8-amino quinolines, 6-methoxy-8-B diisobutylaminoethylamino quinoline dihydrochloride (SN2842) and 6-methoxyl-8-diisobutylaminoisopropylamino quinoline dihydrochloride (SN-3501), have been found to possess a relatively high degree of chemotherapeutic activity in schistosomiasis in mice The drugs were administered in the diet in varying concentrations to mice injected intraperitoneally with 100 to 125 cercariae of schistosoma mansoni shed from snails of the species *Australorbis glabratus* Therapy was started 4 to 6 weeks after infection and continued for 1, 2, or 4 weeks Mice were autopsied 1 or 2 weeks after therapy was discontinued The number of worms in the portal and mesenteric veins and liver were counted When mice were treated with SN3501 in a concentration of 0.1% for 2 weeks 85% of 32 mice contained no worms at autopsy, compared with 10% negativity in the controls, and the average number of worms per mouse was 0.25, compared with 8.4 per mouse in the controls With SN2842 in the same concentration and for the same duration of therapy 97% of 39 mice were completely negative for worms, compared with 12% of control mice, and the average number of worms per mouse was 0.1, compared with 9.5 per mouse in the controls Eleven other 8-amino quinolines tested were found to be relatively inactive Neither SN3501 nor SN2842 showed activity as a prophylactic when administered simultaneously with infection for a period of 2 weeks in a concentration of 0.1%

Depressor action of nitrate esters of alkyl glycolates JOSEPH G BIRD (by invitation), HARRY K IWAMOTO, JOHN B HARMON (by invitation) and JOHN C KRAVITZ, JR *Dept of Pharmacology, Univ of Maryland School of Medicine, Baltimore, Md* A series of nitrate esters of glycolic acid esterified with alkyl alcohols varying from methyl to decyl were prepared Certain physicochemical properties associated with pharmacodynamic responses were investigated Depressor responses elicited, in dogs under anesthesia, by these esters were observed It appears that the depressor response in the series studied increased with decreasing water solubility of the higher esters

Quality and potency determination of analgesics D D BONNICASTLE and JOHN A BIRD, JR (by invitation) *Laboratory of Pharmacology, Yale Univ, New Haven, Conn* Experiments are reported in which a constant dose of morphine

applied to the rat tail and the log-ratio of reaction time before and during the influence of a drug was used as a metameter of response to pain. The mean response of groups of such animals was calculated from truncated distributions. The relation of reaction time to degree of stimulus also was studied. The curves illustrating response/log dose relationship for the individual drugs take various forms, and three main types can be recognized. In one group, (e.g. acetylsalicylic acid) the continuous rise in response levels off asymptotically at about 30% increase in reaction time. A second type (e.g. codeine) presents the same picture at lower doses, but with high doses a secondary rise occurs tending towards an asymptote at about 100%. A third form of reaction curve is a direct rise from 0 to an asymptote of 100%. Intermediate forms between these types may be observed. It is suggested that the two asymptotic levels represent respectively the maximum analgetic, (thalamic?) effect and the maximum hypesthetic (cortical?) effect. These two properties of the drug are measured by the two doses at the respective points of inflection in the first and secondary rises. In the description of the pain-relieving activity of an individual chemical compound these two constants may serve to indicate a) simple analgetic potency, and b) narcotic activity, respectively.

Binding of streptomycin to plasma proteins
G. E. BOXER, V. C. JELINEK (by invitation), and A. O. EDISON (by invitation) *Research Laboratories of Merck & Co., Inc., and the Merck Institute for Therapeutic Research, Rahway, N. J.* Elsewhere it has been reported that the clearance of streptomycin is about 70% of the simultaneously measured glomerular filtration rate. The possibility that protein binding made part of the streptomycin present in the plasma unavailable for filtration through the glomerulus was investigated. Two techniques were employed to measure protein binding: 1) Measurement of the distribution of streptomycin on both sides of a cellophane membrane after dialysis of dog plasma against a Ringer solution containing varying amounts of streptomycin. 2) Determination of streptomycin in the ultrafiltrate of plasma containing varying amounts of the drug. The dialysis experiments indicated $33 \pm 3\%$ and the ultrafiltration experiment $35 \pm 4\%$ binding of streptomycin to the plasma proteins of the dog. Within the range tested, 5 to 100 γ /ml, the percentage of streptomycin bound was independent of the concentration of the drug but dependent on the protein concentration. Both albumin and globulins are responsible for the binding. The observed protein binding accounts quantitatively for the observed clearance of streptomycin at about 30% below the simultaneously measured glomerular filtration rate.

Indirect in vitro action of antibiotics in com-

parison with activity of accepted amebicides
JOHN L. BRADIN, JR., and EDER L. HANSEN (introduced by HAMILTON H. ANDERSON) *Division of Pharmacology and Experimental Therapeutics, Univ. of California Medical School, San Francisco, Calif.* A comparative study has been carried out which reveals differences in amebicidal levels between tests performed in cotton-stoppered versus vaseline-sealed cultures (see abstract by Hansen, *Federation Proc.*, this issue). As a base line for the antibiotic studies, the method has been applied also to retest representative amebicides, such as carbarsone, carbarsone oxide, emetine, vioform, diodoquin, and two thioarsenites (C.C. 914 and C.C. 1037). All antibiotics tested to date have shown some degree of bacteriostatic activity, and death of the ameba in cotton-stoppered tubes is shown to be due to inhibition of growth of the associated bacteria rather than to direct action of the antibiotic on *E. histolytica*. It has been shown previously (Bradin, in press) that death of the ameba, following exposure to an antibiotic which produced bacteriostasis, could be correlated with a shift in oxidation-reduction potentials of the cultures from negative to positive levels. Chang (1946) had reported that such positive levels constitute an environment lethal to this protozoan. It is, therefore, suggested that the indirect amebicidal activity, in the case of the antibiotics observed in cotton stoppered cultures, is due, at least in part, to this phenomenon. Data are presented showing oxidation-reduction levels in cotton-stoppered and in vaseline-sealed cultures.

Inhibition of cholinesterase activity of human blood plasma II. Studies with hexaethyltetrapolyphosphate containing C¹⁴
RALPH W. BRAUER and RITA L. PESSORRI (by invitation) *Dept. of Pharmacology and Experimental Therapeutics, School of Medicine, Louisiana State Univ., New Orleans, La.* The mechanism of the interaction between plasma (cholin) esterase and neutral phosphate ester type inhibitors (e.g. hexaethyltetrapolyphosphate (HETP), Tetraethylpyrophosphate (TEPP)), has been studied in a previous paper (Ralph W. Brauer, *J. Pharmacol. & Exper. Therap.* 92: 162, 1948). Work to be reported represents an extension of that earlier investigation along the following lines: 1) HETP containing C¹⁴ in the alkyl groups (alpha carbons) has been prepared. This material is being used to investigate whether the enzyme inhibition involves the fixation of any part of the inhibitor molecule upon the inhibited enzyme. The previous study had shown that the P-containing moiety is not firmly attached to the enzyme, and that enzyme inhibition is paralleled by disappearance of inhibitor. 2) The addition of F⁻ in amounts which do not affect the enzyme to aqueous solutions of HETP or TEPP markedly delays the loss of anticholinesterase activity, ob-

served under these conditions in the absence of fluoride. This reaction is described in detail, and discussed in relation to the enzyme-inhibitor reaction. 3) *In vivo* studies of the rate of recovery of liver and plasma cholinesterase activities of male rats after Di-isopropyl fluorophosphate (TEPP) and p-nitrophenyl thiophosphate administration are reported.

A single injection method for the assay of digitalis in pigeons. H. A. BRAUN and L. M. LUSKY (by invitation) *Division of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D. C.* A comparative study of digitalis assay has been made using a single-injection pigeon method, the USP XIII intravenous infusion cat method, and the intravenous infusion pigeon method (*J. Pharmacol. & Exper. Therap.* 93: 81, 1948). In the single injection method, digitalis dilutions were injected into the alar veins of pigeons at 3 dosage levels. Six pigeons were used on each dose. Death occurred in from 3 minutes to 1 hour. The slope of the dosage mortality curve is very steep (on the order of 40 probits/log dose) and as a result the standard error of the assay is small. This method results in a considerable saving in time over the infusion methods. Assays by the 3 methods have been completed on a number of digitalis preparations of various types with good agreement between methods.

Evaluation of several types of drugs and combinations against anaphylaxis in guinea pigs. BARBARA B. BROWN (by invitation) and HAROLD W. WERNER *Pharmacology Dept., Research Laboratories, Wm. S. Merrell Co., Cincinnati, Ohio.* Eight compounds possessing parasympathetic depressant, sympathomimetic, or direct smooth muscle depressant action were evaluated for antianaphylactic activity in guinea pigs actively sensitized to horse serum. Activity was determined following intraperitoneal injections of each compound and of combinations of each with a maximal noneffective dose of the antihistamine, Decapryn Succinate. The direct smooth muscle depressants, papaverine and Butaphyllamine (theophylline isobutanolamine), considered as a group were the most effective antianaphylactic agents both alone and in combination with Decapryn. Two of the parasympathetic depressants, atropine and Diocyl (diethylaminoethyl 1-cyclohexylcyclohexanecarboxylate), failed to protect against anaphylactic death, but doses of 6 to 14 mg/kg injected with the noneffective dose of Decapryn reduced mortality by about 60%. A new parasympathetic depressant which also has direct smooth muscle depressant action, 2,2-diphenyl-4-dimethylaminomethyl-1,3-dioxolane methobromide, was ineffective alone but reduced mortality to a minimum when combined with Decapryn. Two sympathomimetic amines, Nethamine (N-ethylephedrine) and N-methyl-

N-cinnamyl-2-phenylpropylamine, had no action alone but caused a significant reduction in mortality when employed in 6 to 17 mg/kg doses with the antihistamine. A test of one triple combination composed of noneffective doses of Butaphyllamine, Nethamine, and Decapryn demonstrated marked potentiation of action. These results indicate that certain combinations of drug actions may prove valuable in allergic bronchial asthma.

Adrenergic-like action of acetylcholine on the isolated rabbit heart. H. D. BRUNER and KWANG SOO LEE (by invitation) *Dept. of Pharmacology, Univ. of North Carolina, Chapel Hill, N. C.* The apparent adrenergic action of acetylcholine on atropinized isolated mammalian hearts has been further analyzed by adding tetraethylammonium Br, nicotine, d-tubocurarine, F-933, dihydroergocornine, ergotamine, dibenamine and priscol to the isolated rabbit heart perfused by the Langendorff technique. The findings throughout confirm the possibility suggested by Hoffman *et al.* (*Am. J. Physiol.* 144: 189, 1945) that there are ganglion cells on these hearts whose activities are to be classed as adrenergic. The dose of acetylcholine necessary to produce the adrenergic effect is some 10 to 100 times that to produce an intense typical cholinergic effect. No evidence has been found that acetylcholine has a direct myotropic action on ventricular muscle. Acetyl- β -methyl choline does not elicit the response.

Oral Activity of Analogues of 3-ortho-toloxyl-1,2-propanediol. JOHN C. BURKE, RICHARD K. THOMS, G. LEE HASSERT, JR. and RITA J. WILKINS (introduced by CHARLES R. LINEGAR) *Pharmacological Development Division, E. R. Squibb & Sons, New Brunswick, N. J.* In June 1948 Berger and Schwarz (*J. A. M. A.* 137: 772) reported that 3-ortho-toloxyl-1,2-propanediol (Tolserol) is effective by oral administration for the relief of various spastic conditions. One of the chief limitations to such use is its short duration of action. In an attempt to overcome this difficulty, a large series of compounds, synthesized and screened in Squibb Institute for Medical Research (*Tr. New York Acad. Sci.* 2: 11, 2-5, 1948) for possible intravenous use, were reviewed. Seven of these compounds were selected on the basis of their intraperitoneal potency in mice and their solubility and screened for their depressant action orally in mice. Compounds with lower solubility than Tolserol showed for the most part a slower onset and longer duration of action. Solutions of Tolserol have as much as three times the activity as high concentration suspensions but a shorter duration of action. Two compounds of the series 2-ortho-toloxyl-1,2-propanediol and 3-thymyloxy-1,2-propanediol, showed the most advantageous combination of oral potency and duration of action in mice. The 3-thymyloxy compound proved irritant at 100 mg/kg.

level studies in dogs showed that the absorption of the latter compound was delayed but more prolonged and constant than that of Tolserol

Trichloroethanol as a metabolic product of trichloroethylene THOMAS C BUTLER *Dept of Pharmacology and Experimental Therapeutics, Johns Hopkins Univ, Baltimore, Md* When urine from dogs that have inhaled trichloroethylene vapor is acidified and heated, trichloroethanol is formed, presumably by hydrolysis of the glucuronide, urochloralic acid Trichloroethanol is produced in larger amounts from trichloroethylene by the dog than is trichloroacetic acid, a metabolic product previously identified (Barrett and Johnston, *J Biol Chem* 127 765, 1939, Powell, *Brit J Indus Med* 2 142, 1945) The immediate precursor both of trichloroethanol and of trichloroacetic acid may be chloral hydrate

Influence of alpha-naphthylthiourea (ANTU) on iodine metabolism RICHARD U BIERRUM (by invitation), KENNETH W COCHRAN (by invitation), and KENNETH P DuBOIS *Univ of Chicago Toxicity Laboratory and the Dept of Pharmacology, Univ of Chicago, Chicago, Ill* Previous work in this laboratory has shown that the administration of iodide will protect rats against several lethal doses of ANTU while thyroidectomized rats are not protected by iodide We have, therefore, studied the effect of acute ANTU poisoning on iodine metabolism Thyroids of normal rats fed a synthetic diet had an average iodine concentration of 129 mg % Five hr after a lethal dose (10 mg/kg) of ANTU there was a 50% decrease in thyroid iodine Twenty-four hr after a sublethal dose (4 mg/kg) of ANTU thyroid iodine was one-third the normal level When normal rats were fed a diet containing 5.3 mg I/gm of diet for 2, 5, and 10 days the average iodine values increased to 201, 270, and 297 mg % respectively for the 3 feeding periods Various tissues from thyroidectomized rats contained as much iodine as those from normal rats after similar iodide feeding periods Guinea pigs which have about 1/3 the thyroid iodine concentration of rats exhibited an increase in thyro iodine and a decrease in thyroid weight with an overall loss in total iodine after 200 mg/kg of ANTU Feeding iodide failed to protect guinea pigs against ANTU and failed to increase the thyroid iodine concentration ANTU inhibited the uptake of I^{131} by rat and guinea pig thyroids Doses of 1 and 10 mg/kg of ANTU to rats caused respectively 50% and 90% inhibition and 150 mg/kg to guinea pigs caused 95% inhibition of thyroid uptake of I^{131}

Relation of chemical structure to action of hyaluronidase inhibitor B CALESNICK and K R. BUETNER (introduced by R. BUETNER) *Dept of Pharmacology, Hahnemann Medical College and Keeley Inst, Dwight, Ill* A search was undertaken

for chemically related substances which inhibit hyaluronidase For testing hyaluronidase activity, we used the turbidimetric method by Kass and Seastone which is based on the precipitation of acidified horse serum by potassium hyaluronate Hyaluronate and hyaluronidase were incubated with or without the substance investigated The decomposition of hyaluronate was then tested by adding horse serum Phenol proved to be active 1 mg inactivating 7.5 gammas of hyaluronidase, 1 mg of cresol, 24 gammas, ortho cresol, 37.5 gammas per mg, chlorine substitution products more With longer side chains attached to phenol, the activity rises higher 1 mg of diamyl phenol inactivates 600 gammas (0.6 mg) and hexylresorcinol, 400 gammas (0.4 mg) while the unsubstituted resorcinol is close to phenol in activity In contrast salicylic acid proved to be only feebly inhibiting, 1 mg inhibiting only 5.0 gamma of hyaluronidase These drugs were added to the testing mixture dissolved in alcohol which has no anti-enzymatic effect in the amounts used The therapeutic use of massive doses of sodium salicylate in rheumatic fever may be explained by its low inhibiting power Sodium gentisate, a metabolic product of salicylate, inhibits even less Many anti-histamine drugs are known to restrict the spreading of a subcutaneously injected dye after hyaluronidase, but we found that these drugs do not inhibit hyaluronidase *in vitro* Also, epinephrine which restricts spreading, does not inhibit hyaluronidase but enhances it

Method for assaying potential coronary vasodilators A CAMERON (by invitation), E SORENSSEN (by invitation) and B CRAVER *Division of Macrobiology, Research Dept, Ciba Pharmaceutical Products, Inc, Summit, N J* In the Langendorff preparation of the perfused mammalian heart, primary effects upon the coronary circulation may be difficult to distinguish from effects secondary to changes in rate or the amplitude of the contractions In studying a series of mono and dialkyl amino derivatives of histamine, it was found that a better appraisal of the effects of these derivatives upon the actual coronary circulation could be achieved by perfusing the heart with a recycled perfusion fluid to which one microgram/ml of 2-(Beta-naphthyl)imidazoline hydrochloride (Privine) had been added The addition of 0.035-0.1 IU/ml of Pituitrin served almost as well but was somewhat less consistent in its action This usually allowed the progressive development of a decreased coronary flow which only after many minutes adversely affected the rate and amplitude of the myocardial contractions The addition of histamine or various derivatives of histamine to the perfusion fluid containing the Privine promptly led to a marked increase in the coronary flow, soon thereafter to an increase in rate, and finally to an

increase in the amplitude of the myocardial contractions. This order of changes bespeaks therefore a direct effect of the drugs upon the coronary circulation. This argument is strengthened by the effects of Pituitrin itself upon the isolated heart, since low doses can exert a considerable positive inotropic action, especially upon the hearts from younger animals with a presumed greater reserve of coronary flow. This balancing of two opposed effects has also been observed with Prinine.

Arsenic content of normal hair in the Chicago area. W. J. R. CAMP and V. A. GAST (by invitation) *Dept of Toxicology, Univ of Illinois, Chicago, Ill.* Because arsenic effects symptoms mimicing those of many pathological conditions physicians frequently consider arsenic intoxication in differential diagnosis. Arsenic determination was requested in 18.5% of our cases for the year 1948. Hair is commonly submitted for analysis since it is simpler to collect than a 24 hr urine specimen. In order to establish the amount of arsenic found in the hair of healthy normal individuals in the Chicago area, a series of 13 samples were analyzed by the Gutzeit method with an average of 0.51 μg of arsenic calculated as arsenic trioxide and a range of 0.25 to 0.88 $\mu\text{g}/\text{gm}$ of hair. While these figures are somewhat lower than those of Künkele and Fordyce, Rosen and Myers, they agree reasonably well with those reported by Glaster. Since there is no way to differentiate 'interior' and 'exterior' arsenic the amount normally found will probably vary from area to area depending on the dietary habits of the community, the amount of smoke and soot in the atmosphere, etc. We did not find any clear cut difference with age (6-52 yr), nor between smokers and non smokers, nor between those who did and did not eat sprayed fruit.

Maintenance of *T. equiperdum* in vitro at 38 C. WILLIAM CANTRELL (introduced by E. M. K. GEILING) *Dept of Pharmacology, Univ of Chicago, Chicago, Ill.* A modification of the technique of Geiman, Anfinson, McKee, Ormsbee and Ball for the cultivation of malaria parasites was used to maintain *Trypanosoma equiperdum* in vitro at 38 C. An increase in numbers of about 50% was observed during the first 4 hours when 40 mg/l ascorbic acid and 160 mg/l glutathione were added to the perfusion medium which contained casein hydrolysate, glucose, pyridoxine, nicotinic acid, nicotinamide, riboflavin, thiamin, calcium pantothenate, choline, and the inorganic salts of the medium of Geiman and coworkers. The trypanosomes were maintained in 14 ml defibrinated rat blood as both citrate and heparin had an adverse effect. The blood was placed in a glass tube 5 cm in diameter and 10 cm long with one end covered with cellophane and suspended in 250 ml of the perfusion medium. Small glass covered magnets in the blood phase

and in the perfusion medium were used to promote diffusion through the membrane and to keep the trypanosomes in suspension. The medium was sterilized by filtration.

Comparative studies of dihydroergot derivatives. R. T. CAIRNS (by invitation), H. M. SLECKLE (by invitation) and O. SIDNEY ORTH *Depts of Pharmacology and Neurosurgery, Univ of Wisconsin Medical School, Madison, Wis.* Alterations of some of the pharmacological properties of the ergot alkaloids due to hydrogenation have been reported for dihydro derivatives of ergotamine and ergocornine. The present study is concerned with 2 additional hydrogenated derivatives, viz, dihydroergocristine (D.C.S. 90)- and dihydroergokryptine (D.H.K. 135). Sandoz Comparisons have been made of the 4 derivatives for both acute and chronic toxic quantities, pathological changes in the heart, lung, liver, spleen, and kidney, and pharmacodynamic actions on the cardiovascular system and gastrointestinal tract. Protection was found against cardiac irregularities which occurred spontaneously during the administration of various anesthetic agents or were initiated by epinephrine injections. Augmentation of movement of the gastrointestinal tract was observed.

Cyclic and noncyclic hydrocarbons and cardiac automaticity. C. JILLIFF CARR and JOHN C. KRANTZ, JR. *Dept of Pharmacology, Univ of Maryland School of Medicine, Baltimore, Md.* The inhalation of 12 different hydrocarbons by the dog was found to produce a sensitization of the myocardium to epinephrine. The compounds studied were ethane, propane, propylene, cyclopropane, n-butane, isobutane, cis-trans-butene-2, cyclobutene, cyclobutane, cyclopentane, isopentane, and 2,2 dimethyl-butane. Ethylene inhalation did not sensitize the myocardium under similar experimental conditions. In an attempt to explore further this unique character of ethylene, additional compounds have been tried, including methylene cyclobutene, methyleyclobutane, cyclopentene, spirocyclopropane, ethylene oxide, propylene oxide and acetylene. Mixtures of cyclopropane and ethylene were found to produce a sensitization of the dog's myocardium in a manner similar to that observed with pure cyclopropane.

Curariform action of decamethylene-1,10-bis-trimethylammonium bromide. JULIO C. CASTILLO (by invitation) and EDWIN J. DE BEER *Wellcome Research Laboratories, Tuckahoe, N. Y.* Confirming the findings of Barlow and Ing, and Paton and Zaimis (*Nature* 161: 718, 1948) on the curariform action of polymethylene bisquaternary ammonium salts of the general formula $(\text{CH}_2)_n\text{N}^+(\text{CH}_3)_3\text{N}^+(\text{CH}_3)_3\text{Br}^-$, the decamethylene (C_{10}) member of the series has been found to have a curare-like activity exceeding that of d-tubocurarine chloride (d.t.c.), the potency varying with the species and

the method of test. It is less toxic and it causes less embarrassment of the respiration than d t c. In cats and dogs the intravenous injection of a curarizing dose of C_{10} causes no significant change in blood pressure unless a big dose sufficient to depress the respiration is given, in which case a typical asphyxial rise in blood pressure is observed. The curare-like action of C_{10} is not antagonized by prostigmine in doses adequate to antagonize the effect of d t c, but in certain cases appears to be antagonized by the C_6 member of the series. An interesting finding is the fact that if a dose of C_{10} is preceded by a dose of d-tubocurarine chloride, the curarizing action of C_{10} is markedly inhibited.

N-(p-arsenoso-benzyl)-glycineamide HCl as an amebicide, *in vitro* and *in vivo* in macaques. Y. T. CHANG and R. K. REED (introduced by HAMILTON H. ANDERSON) *Division of Pharmacology and Experimental Therapeutics, Univ of California Medical School, San Francisco, Calif.* The substituted phenyl arsine oxide (NU-1067 supplied by Dr. E. L. Sevringhaus) contains 26% arsenic. It occurs as a stable white powder and is reportedly less toxic for mice, rats, and rabbits than o-phenarsine HCl. It has shown activity against trypanosomes, treponema, and borrelia. Since it is stable in solution, in contrast to many arsenoso compounds, a comparison of its amebicidal activity was made with mapharsen. *E. histolytica*, grown in egg slope medium, after 48 hours' exposure at 37°C (with a single bacterial associate, organism 't'), was killed by mapharsen at 1:40,000. NU-1067 was active within the range of emetine HCl (1:20,000). Mapharsen was active in monkeys only during the period of therapy, when given in toxic amounts (Anderson and Hansen, 1947). NU-1067 was administered at various dose levels to 11 macaques. Two received 25 and 50 mg/kg, intravenously, total for 5 days without clearance of *E. histolytica*. Two were given orally 30 and 100 mg/kg total for 10 days with clearance of amebas for 6 weeks at the higher dose level. Two monkeys, similarly treated with 300 mg/kg, were cleared of amebas during 3 months' follow-up in one. One developed edema of the genitalia and increased urea-N (20 mg %) as well as depressed 'T' waves on the electrocardiogram. At 450 mg/kg, similarly administered, 2 were cleared over 3 months. At 650 mg/kg, similarly given, one was cleared. The other received identical treatment, had increased urea-N (32.5 mg %) and depressed 'T' waves also. At 1.0 gm/kg orally for 10 days, the urea-N after therapy was 20 mg %. Thus, NU-1067, like mapharsen, was amebicidal *in vitro*, but in macaques amounts that cleared natural infections were within the toxic range.

Action of diphenhydramine (benadryl) in reversing the epinephrine reversal of blood pressure. GRAHAM CHILN and DAVID RUSSELL (by in-

itation) *Research Laboratories, Parke, Davis and Co., Detroit, Mich.* Diphenhydramine, 5 to 10 mg/kg, was found to reverse the 'epinephrine reversal' of blood pressure of a dog, previously receiving an adrenergic blocking agent. A number of the para-substituted derivatives of diphenhydramine and cocaine in larger doses can produce the same effect. Since these compounds also potentiate the pressor effect of epinephrine, this and the action in reversing the 'epinephrine reversal' of blood pressure may be similar in nature. The blocking of the vasodepressor receptors is suggested as a possible mode of action of these compounds on the vasopressor response to epinephrine.

Comparison of the cardiac action of thevebioside and nerifolin with thevetin. K. K. CHEN, ROBERT C. ANDERSON (by invitation), and FRANCIS G. HENDERSON (by invitation) *The Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, Ind.* Since the isolation of thevetin in our laboratory from the nuts of *Thevetia nerifolia*, a newer glycoside, nerifolin, has been independently obtained by Frèrejacque (*Compt. rend.* 221: 645, 1945) and Helfenberger and Reichstein (*Helvet. Chim. Acta* 31: 1470, 1948). By careful hydrolysis of thevetin with strophanthobase, the latter succeeded in splitting 2 molecules of glucose, one by one, and separating in crystalline form 2 simpler glycosides, thevebioside and nerifolin. The last was identical with that occurring in nature. The digitalis-like action of either thevebioside or nerifolin was easily demonstrated by the systolic standstill of the frog's ventricle, and the characteristic changes of the cat's electrocardiogram. By comparison with thevetin, nerifolin was found to be about $4\frac{1}{2}$ times as active in cats, and 3 times as active in frogs, as shown in the table. Thevebioside showed a higher potency in frogs, but was not much different from thevetin in cats. The median emetic doses were determined in both cats and pigeons.

	Thevetin	Thevebioside	Nerifolin
Cat Mean LD $\mu\text{g/kg}$	889.0 ± 31.0	1004.0 ± 103.8	196.1 ± 10.3
Frog SD $_{50}$ $\mu\text{g/g}$	6.35 ± 0.20	3.78 ± 0.57	2.03 ± 0.19
Cat EmD $_{50}$ $\mu\text{g/kg}$	300.0	161.0	64.7
Pigeon EmD $_{50}$ $\mu\text{g/kg}$	211.8 ± 13.8	141.0 ± 19.0	110.6 ± 11.6

Prevention of fluoroacetate poisoning by acetate donors. MAYNARD B. CHENOWETH, EDWARD B. SCOTT (by invitation) and S. LOUISE SEKI (by invitation) *Dept of Pharmacology, Univ of Michigan Medical School, Ann Arbor, Mich.* The depression of contractility of isolated, perfused rabbit hearts or intestine induced by sodium fluoroacetate (FA) can be prevented by prior addition of sodium acetate. However, little or no protection of the intact rabbit can be obtained with even very large doses of sodium acetate. Administration of acetate

as monoacetin in doses of 2-4 gm/kg one-half hour before a certainly lethal dose of FA (0.5 mg/kg) prevented any symptoms of FA poisoning in 27 of 36 rabbits, while of 26 rabbits receiving the same dose of FA, 26 died. Alkalosis induced by sodium bicarbonate, fumarate or hydroxide greatly shortens the time to death of FA poisoned rabbits, probably explaining failures with sodium acetate. Five dogs receiving 0.1 mg/kg FA died in an average of 330 minutes while of 14 dogs receiving a total of 5 gm/kg monoacetin before and after the same FA dose, 5 survived without showing symptoms of FA poisoning. Average time to death of remainder of this group was 600 minutes. Monoacetin administration during the latent period characteristic of FA, or acute stages of poisoning, is without much effect. Monoacetin appears to be specific against FA and its congeners. That it acts by delivering a useful acetate moiety is indicated by the fact that it is equally or more effective than equimolar amounts of sodium acetate in increasing the acetylation of PABA by the rabbit. Some other acetate donors appear to be effective FA antagonists and will be reported upon.

Effect of local anesthetics on the motility of isolated rabbit ileum. GEORGE P. CHINN (introduced by ROBERT A. WOODBURY) *Dept of Physiology and Pharmacology, Albany Medical College, Albany, N. Y.* The spasmolytic action of a number of local anesthetics was studied using segments of isolated rabbit ileum. Most of the tests were made with Nupercaine, Pontocaine, Butacaine, Larocaine and Procaine. With the exception of Procaine these drugs decrease the normal motility of the ileum and relieve the spasm induced by Acetyl Choline and Barium Chloride. Their effectiveness on the intestine parallels their action as local anesthetics. 0.02% Procaine increases the amplitude of contractions, 0.04% increases amplitude and tone, 0.06% decreases the amplitude with increased tone, 0.1% decreases both amplitude and tone, acting like the other local anesthetics. The stimulating action of Procaine is not inhibited by Atropine. The action of these drugs appears to be neurotropic and musculotropic and is completely reversible on changing the bath. The question as to whether part of their effect is due to their action as local anesthetics is difficult to answer. Many synthetic antispasmodics also possess local anesthetic properties. The rapidity with which they often act in relieving the pain of peptic ulcer suggests that their success may be due in part to this local anesthetic action. Preliminary clinical trials with the local anesthetics indicate that they are effective in relieving pylorospasm, cardiospasm and the pain of peptic ulcer.

Action of synthetic antispasmodics and local anesthetics on human gastric motility. GEORGE P. CHINN (by invitation) and ROBERT A. WOOD-

BURY *Dept of Physiology and Pharmacology, Albany Medical College, Albany, N. Y. and Dept of Pharmacology, Univ of Tennessee Medical College, Knoxville, Tenn.* The synthetic antispasmodic, diethylamino ethyl phenyl thienyl acetate, Asymatrine, was found to be very useful in the relief of cardiospasm, pylorospasm, the pain of peptic ulcer and other gastro enteric conditions. Some patients, however, volunteered the information that Asymatrine often produced a painless increased gastric motility. The action of Asymatrine and other antispasmodics on the motility of the human stomach was studied with intragastric balloons. Using Urecholine as the spasmogenic drug, Atropine, Homatropine, Papatrine, Triisentin and Syntropin were spasmolytic in that order. Asymatrine, however, sometimes increased and sometimes decreased the motility. A comparison of the spasmolytic action of these drugs using isolated rabbit ileum with Barium Chloride and Acetyl Choline as spasmogenic agents, showed that Asymatrine was better than the others against Barium but not as good as Atropine or Homatropine against Acetyl Choline. A study of the local anesthetic action of these compounds showed that Asymatrine produced the best anesthesia of the rabbit cornea. On the basis of these apparently paradoxical results and a study of the spasmolytic action of a series of local anesthetics, Procaine, Butacaine, Larocaine, Pontocaine and Nupercaine were tried clinically for the relief of the pain of peptic ulcer, pylorospasm and cardiospasm with gratifying results. It is suggested that local anesthetics be given a clinical trial in other conditions for which antispasmodics have been used.

Toxicology and pharmacology of lupulon. YIN-CH'ANG CHIN (by invitation) and HAMILTON H. ANDERSON *Division of Pharmacology and Experimental Therapeutics, Univ of California Medical School, San Francisco, Calif.* Lupulon, an antibiotic derived from hops (*Humulus lupulus*, L.) has been reported to be active against experimental mouse infections of *Mycobacterium tuberculosis* (Chin, Y. C., et al., *Proc Soc Exp Med*, in press). The results so far obtained in toxicologic and pharmacologic studies follow. Intragastric LD₅₀'s in mice, rats and guinea pigs were 1500, 1800 and 130 mg/kg, respectively. The intramuscular LD₅₀ was 600 mg/kg for mice and 330 mg/kg for rats. Convulsions were observed in animals which received lethal or sub-lethal intragastric or intramuscular doses. Daily intragastric administration of lupulon for 12-14 days resulted in a slight suppression of growth of young rats which received 450 and 300 mg/kg, but not in those given 150 mg. A slight decrease in weight of rabbits occurred after 300 mg/kg daily, and an increase of weight occurred in guinea pigs after 30 mg/kg/day over 14 days. Hemoglobin, RBC and WBC determinations in these ani-

mals were within the normal range. Intramuscular doses of 60 mg/kg/day for 30 days were tolerated without gross effects in mice. Lupulon, 4% added to diet, caused deaths in 50% of mice within 18 days, while 75 and 90% survived 40 days on food which contained 2 and 1%, respectively. All mice lost weight, which was less with lower doses. Neither hemolysis of rabbit erythrocytes nor loss of motility of leukocytes occurred *in vitro* within the effective antibiotic range. Respiratory stimulation was observed following intravenous injection of lupulon in both anesthetized and unanesthetized animals.

Ganglionic blocking action of diethylaminoethanol BYRON B. CLARK and MAURICE M. HELPERN (by invitation) *Dept of Pharmacology, Tufts College Medical School, Boston, Mass.* Recent quantitative studies show that diethylaminoethanol (DEAE) is rapidly formed after the intravenous injection of procaine, and that DEAE has therapeutic actions in man similar to procaine intravenously, with less toxicity (Brodie and co-workers, unpublished). Evidence for a ganglionic blocking action was obtained from the following observations on pentobarbitalized dogs and cats. DEAE-HCl injected intravenously in 30-60 seconds produces a prompt vasodepression of about 50% lasting 5-45 minutes with doses of 28 to 212 mg/kg. In the cat the inhibition of the contraction of the nictitating membrane to preganglionic stimulation paralleled the vasodepression, while postganglionic stimulation remained fully effective. The pressor response to splanchnic nerve stimulation was inhibited during DEAE vasodepression in adrenalectomized dogs, but typical pressor responses were obtained with the adrenals intact, and with injected epinephrine. Atropinization did not alter the vasodepressor response to DEAE. The heart rate is decreased about 10-25% during the vasodepression, and the vasodepressor and chronotropic effects on the heart of vagal stimulation are inhibited. In addition, the chronotropic effect of epinephrine on the heart appears to be inhibited (DEAE has been shown to protect against epinephrine-cyclopropane ventricular tachycardia in dogs—Brodie). DEAE has a positive inotropic effect on the isolated rabbit heart. On isolated intestine and uterus DEAE was found to have no significant cholinergic, anticholinergic, antihistaminic activity, or spasmolytic action against barium chloride. It does not antagonize the inhibitory action of epinephrine on intestine, but may have an adrenolytic action in high concentrations on rabbit uterus. The present evidence indicates that a major action of DEAE is to block transmission at autonomic ganglia.

Effect of fluoroacetate on oxidative processes in frog muscle DONALD A. CLARKE (by invitation), JAMES F. TOOLE (by invitation) and WALTER F.

RIKER *Dept of Pharmacology, Cornell Univ Medical College, New York City* The exposure of intact frog sartorii to varying concentrations of methyl fluoroacetate (1080) results in the disappearance of the recovery heat associated with contraction, the initial heat as well as the mechanical response remains unaltered. This indicates that fluoroacetate interferes with oxidative recovery processes in contracting muscle. Concentrations of sodium or methyl fluoroacetate as high as 10^{-3} M are without effect on the oxygen consumption of resting muscle. In contrast, however, a fluoroacetate concentration of 10^{-3} M produces a profound depression of the excess oxygen consumption which is associated with the action of caffeine. This suggests that fluoroacetate, like azide and hydroxylamine, is capable of differentiating the resting from the activity oxidative processes. In contrast to azide it does not inhibit the cytochrome oxidase system. To define further the locus of action, various intermediates of the carbohydrate cycle were added to the caffeine stimulated muscles poisoned with fluoroacetate. The substances tested were lactate, succinate, pyruvate, glucose, fumarate, acetate, ketoglutarate, tartrate, and ATP. Of these, only pyruvate significantly antagonized the effects of fluoroacetate. A concentration of 10^{-2} M sodium pyruvate restored completely the activity oxygen consumption of the fluoroacetate poisoned muscles.

Loss of As from tissues by volatilization RANDOLPH CLEMENTS, J. EUGENE HILL and HERSHAL G. TREE (by invitation), P. L. EWING and G. A. EMERSON *Dept of Pharmacology, Univer of Texas Medical Branch, Galveston, Texas* As-balance studies were made with mice and rats treated repeatedly with oral doses of K arsenite, Fe arsenate and Fe arsenate plus kaolin, or with water and sludge samples from a Texas stream which had been heavily polluted with Na arsenite and then treated with FeSO_4 and lime. Recovery of As from animals analyzed immediately after oral or intraperitoneal treatment with any of these dosage forms was essentially quantitative by either the A O A C official Gutzzeit or bromate method. On repeated treatment, the balance between the amount given and the amount recovered in the excreta plus tissue As left a deficit of 30-60%, depending upon dosage. Less than 1% of the 'lost' As was recovered from the air by bubbling through concentrated HNO_3 , with a group of rats maintained in a bell jar for two weeks and given daily injections of 5 mg/kg of As_2O_3 as K arsenite. After absorption of inorganic As, the As must be in part converted into volatile substances which either are not absorbed by efficient bubbling through HNO_3 or are retained in the tissues and are volatilized on treatment with H_2SO_4 and HNO_3 .

Toxicity of N-p-chlorophenyldiazothourea

(promurit) to mammals KENNETH W COCHRAN (by invitation) and KENNETH P DuBois *Univ of Chicago Toxicity Laboratory and the Dept of Pharmacology, Univ of Chicago, Chicago, Ill* N-p-chlorophenyldiazothiurea (Promurit) has been employed as a rodenticide in Germany. The chemical similarity of Promurit to alphanaphthylthiourea (ANTU) made it of interest to compare the toxicity and pharmacological effects of the two compounds. For injection propylene glycol solutions of Promurit were employed. The approximate LD_{50} values in mg/kg after intraperitoneal injection were: female albino rats, 0.2; mice, 1.35; guinea pigs, 1.9; and rabbits, 1.75. The approximate LD_{50} for Promurit given orally to female rats was 0.28 mg/kg. The compound is, therefore, more toxic than ANTU. The outstanding pathological change in acutely poisoned animals was pleural effusion. Repeated doses of Promurit resulted in the acquisition of some tolerance. It was acceptable to rats and produced 100% mortality when offered overnight in the diet at concentrations as low as 0.05%. Some increase in blood glucose and a depletion of liver glycogen followed acute poisoning by Promurit. The rodenticide caused a transitory inhibition of tyrosinase and produced a 50% inhibition of peroxidase at a final concentration of 1×10^{-4} M. Feeding iodide to rats before the injection of Promurit resulted in a two-fold increase in resistance toward the rodenticide. Thiosorbitol was ineffective therapeutically against Promurit poisoning while thiourea given prior to Promurit protected against several times the lethal dose. The extremely high toxicity of Promurit and the lack of an antidote appear to limit its possible usefulness as a rodenticide.

Effect of epinephrine on toxicity of procaine
VERSA V COLE and H R HULPIEU *Dept of Biochemistry and Pharmacology, Indiana University, Indianapolis, Ind*. All drugs were given intravenously on a per kg basis. Dogs anesthetized 45 minutes with diethyl ether were infused continuously with 2 mg/min procaine hydrochloride until death. There were 4 groups of 10-12 dogs each as follows: I-controls, II-3 micrograms epinephrine every 5 minutes, III-3 μ g/min for the first 10 minutes of procaine, IV-2.5 μ g/min continuously with the procaine. Two other groups of 5 each anesthetized with thiopental sodium were given 3.5 mg/min procaine hydrochloride until death. Group V were controls, VI received continuous epinephrine as IV. Survival time varied greatly, but averages in minutes were: I-21, II-19, III-17, IV-38, V-56, VI-44. The differences in time between respiratory failure and heart failure in minutes were: I-1.55, II-1.58, III-1.25, IV-0.65, V-2.0, VI-1.1. The blood levels of procaine in mg % at heart failure were: I-3.7, II-3.7, III-2.6, IV-4.4, V-10.7, and VI-7.7. The levels of para-amino benzoic acid in

blood in mg % were: I-0.74, II-0.70, III-0.42, IV-1.54, V-4.9, and VI-4.5. Continuously administered epinephrine in the dose given has a favorable effect on resistance to procaine under ether anesthesia. This effect is not observed under anesthesia with thiopental.

Tetraethyl ammonium and the response of the isolated rabbit heart to nicotine
J M COON, P R SALERNO (by invitation), and L E ELLINWOOD (by invitation) *Dept of Pharmacology, Univ of Chicago, Chicago, Ill*. The isolated rabbit heart gives a biphasic response to a single treatment with 1 mg of perfused nicotine. A complete standstill of about 1 minute duration ceases abruptly to be followed by a marked acceleration and an increase in amplitude lasting about five minutes. Smaller doses of nicotine produce only acceleration. Larger doses elicit a longer period of standstill followed by a more intense stimulation. It is thought that the depression is due to a stimulation of parasympathetic ganglia and that the acceleration may be due to axon reflexes induced in the postganglionic sympathetic innervation. If this were true tetraethyl ammonium (TEA) might be expected to abolish both phases of the cardiac response to nicotine. Perfusion of the isolated heart with 6×10^{-5} M TEA for 10 minutes abolished the inhibitor but not the accelerator response to nicotine. However, 20 minutes perfusion with this concentration of TEA also abolished the accelerator response. Discontinuation of the TEA perfusion was followed by a rapid recovery of the accelerator response, while the inhibitory effect returned more slowly upon washing out with Ringer-Locke solution. If the mechanism of the nicotine action is as described above these findings indicate that the threshold for parasympathetic ganglionic stimulation is higher than that for postganglionic sympathetic fiber stimulation. This would explain the pure cardiac acceleration elicited by small doses of nicotine. Furthermore, the TEA paralysis of the sympathetic fibers appears to be more readily reversible than that of the parasympathetic ganglia.

Comparative activities of five antispasmodics
B CRAVER, W BARRETT (by invitation), A CAMERON (by invitation), A EARL (by invitation), F ROTH (by invitation) *Division of Macrobiology, Research Dept, Ciba Pharmaceutical Products, Inc, Summit, N J*. The activities of 3 known antispasmodics: Trasentine, Trasentine-6H and atropine were compared with those of two new drugs, N-dimethyl thymoxy acetamidine hydrochloride (Su-198), and Thymoxyethyl-diethylamidine hydrochloride (Su-216) in respect to the functions noted. They were examined in respect to the dose in μ g/kg required to inhibit salivation in the cat induced: 1) by histamine, 2) by pilocarpine, and 3) by faradization of the chorda tympani nerve. In order of decreasing activity they were: atropine,

Trasentine-6H, Su-198, Su-216 and Trasentine For each of the 6 drugs, the doses required were essentially the same irrespective of the sialogogic stimulant. The same doses of each drug that inhibited salivation eliminated the spasm of the nictitating membrane induced by subcutaneously injected pilocarpine. To eliminate the hypotension induced by 0.5 y/kg of Mecholyl, approximately a 10-fold increase in the dose of each drug (compared to anti-sialogogic doses) was required. This relationship was strictly quantitative and larger doses of Mecholyl produced hypotension. The order of spasmolytic activity of the 5 drugs remained the same in respect to this function as well as in respect to their ability to eliminate the brief bradycardia and hypotension induced by faradization of the peripheral ends of the severed vagi, but for this latter function only about 5 times the anti-sialogogic doses were needed. The respective LD₅₀'s (I V rats) for the 5 drugs in mg/kg are Su-216—65, Su-198—45, Trasentine-6H—c 37, Trasentine—c 27, and atropine—c 100-125. The problem of attempting to predict the therapeutic usefulness of antispasmodics will be discussed.

Efficacy and toxicity of simaroubidin in experimental amoebiasis ASHTON C. CUCKLER and CARL C. SMITH (introduced by HANS MOLITOR) *Merck Institute for Therapeutic Research, Rahway, N. J.* A standardized procedure has been developed for the evaluation of potential amoebicides in young rats infected with *Endamoeba histolytica*. One of the compounds evaluated in this way, and which is more active therapeutically than many of the currently used amoebicides, is simaroubidin, a crystalline material isolated from the plant *Simarouba amara*. Single oral doses of 25 mg/kg do not have significant amoebicidal activity, whereas single doses of 100 mg/kg % CD₅₀. Single doses of 200 and 400 mg/kg % CD₁₀₀. Six daily doses of 2 mg/kg and 10 mg/kg are ineffective, but doses of 50 mg/kg have significant (>CD₅₀), although not complete, effectiveness. A drug diet of 0.01% given *ad libitum* for 6 days has only slight amoebicidal activity, drug diets of 0.04% and 0.16% % CD₅₀. The acute and chronic toxicities of simaroubidin have been determined for several species. The LD₅₀ for rats and mice of single oral doses was 800 ± 100 mg/kg. In a dog single oral doses of 100 mg/kg produced loss of appetite, but an oral dose of 400 mg/kg was lethal in 2-3 days. Repeated daily oral doses of 500 mg/kg were lethal for 9/10 rats within 10 days, and 250 mg/kg killed 3/12 rats within 21 days. Doses of 50 mg/kg for 21 days produced no mortality and only slight effect on growth of young rats. When the drug was placed in the diet at 0.16% and fed to rats for 21 days the growth was significantly depressed and 1/12 rats died, but no gross pathologic changes were observed at autopsy.

Comparative muscle-relaxing activity of seven

glycerol ethers on isolated nerve-muscle preparations HAROLD DAVIS (by invitation), CHARLES H. HINE and FRANK J. MURPHY (by invitation) *Division of Pharmacology and Experimental Therapeutics and Dept. of Anesthesiology, Univ. of California Medical School, San Francisco, Calif.* Two methods of producing muscular contractions have been adapted for *in vitro* comparison of muscle-relaxing agents. Contractions of frog recti abdomini, suspended in frog Ringer solution (Torda and Wolff, 1944), were recorded. The muscle was stimulated either by physostigmine (2×10^{-4}) plus acetylcholine (10^{-7}) or by tetanic current (100-200 V). In each case the endpoint was arbitrarily designated as 50% reduction of normal contraction following addition of the compound. The duration of exposure to the solution was 30 minutes or less. This technique yielded consistent results. Seven modifications of glycerol ethers, procaine, and Intocostrin were tested. The greatest dilution of each compound which produced an endpoint are listed in the accompanying table. Since the results obtained *in vitro* paralleled those secured in mouse assay procedures, the *in vitro* techniques may serve as a guide to possible muscle-relaxing activity *in vivo*.

Compound	AcCh Eserinized Muscle Stimulation		Electrical Nerve-muscle Stimulation	
	Dilution V/V or W/V	Molarity mM/liter	Dilution V/V or W/V	Molarity mM/liter
Intocostrin (20 u/ml)	10^{-3}	—	10^{-3}	—
Procaine HCl	5×10^{-4}	1.8	5×10^{-4}	1.8
Monocyclohexyl	10^{-4}	0.61	5×10^{-4}	3.0
α, γ isopropyl ethyl	Contraction before endpoint was reached			
α, γ isopropyl tolyl	10^{-3}	0.065	5×10^{-4}	0.33
Phenyl monoacetate	10^{-3}	5.5	5×10^{-4}	2.75
Phenyl diacetate	5×10^{-4}	2.3	5×10^{-4}	2.3
Dibutyl monoacetate	10^{-4}	0.4		
o Toxyl (Myonasin)	10^{-3}	5.5	5×10^{-4}	2.75

Antiepileptic action of Marijuana-active substances JEAN P. DAVIS and H. H. RAMSEY (introduced by LOUIS S. GOODMAN) *Dept. of Pharmacology, Univ. of Utah College of Medicine, Salt Lake City, Utah, and Utah State Training School, American Fork, Utah.* The demonstration of anti-convulsant activity of the tetrahydrocannabinol (THC) congeners by laboratory tests (Loewe and Goodman, *Federation Proc.* 6:352, 1947) prompted clinical trial in 5 institutionalized epileptic children. All of them had severe symptomatic grand mal epilepsy with mental retardation, three had cerebral palsy in addition. Electroencephalographic tracings were grossly abnormal in the entire group, three had focal seizure activity. Their attacks had been inadequately controlled on 0.13 gm of phenobarbital daily, combined with 0.3 gm of Dilantin per day in 2 of the patients, and in a 3rd, with 0.2 gm of Mesantoin daily.

Two isomeric 3 (1,2 dimethyl heptyl) homologs

of THC were tested, Numbers 122 and 125A, with ataxia potencies 50 and 8 times, respectively, that of natural marihuana principles. Number 122 was given to 2 patients for 3 weeks and to 3 patients for 7 weeks. Three responded at least as well as to previous therapy, the 4th became almost completely, and the 5th, entirely seizure free. The optimum dosage was 1.2 to 1.8 mg daily. One patient, transferred to 125A after 3 weeks, had prompt exacerbation of seizures during the ensuing 4 weeks, despite dosages up to 4 mg daily. The 2nd patient transferred to 125A was adequately controlled on this dosage, except for a brief period of paranoid behavior 3½ weeks later, similar episodes had occurred prior to cannabinol therapy. Other psychic disturbances or toxic reactions were not manifested during the periods of treatment. Blood counts were normal. The cannabinols herein reported deserve further trial in non-institutionalized epileptics.

Anti-anemic agents and cholinesterase activity
JOHN EMERSON DAVIS *Pharmacological Laboratory, Univ of Arkansas, Little Rock, Ark.* Considerable evidence is accumulating which indicates that an increase of cholinesterase activity may play an important part in the therapeutic remission of pernicious anemia induced by the administration of liver extract or folic acid. As a further contribution to this evidence, the author has tested the effects of liver extract and folic acid upon the cholinesterase activity of powdered liver (Viobin 40° liver). One mg of pteroylglutamic acid or 0.1 unit of crude liver injection was added to a suspension of 10 mg of powdered liver in 2 cc of tap water. The mixture was incubated at 37° C for 3 hr with occasional agitation or shaking, and then its cholinesterase activity was measured by an electrometric titration method, previously described (*Proc Soc Exper Biol & Med* 63: 287, 1946). When acetylcholine bromide was used as substrate, both liver extract and folic acid caused an average 7-fold increase in the initial hydrolysis rate produced by the powdered liver. When Meecholy chloride was used as the substrate, folic acid increased the enzyme activity of the powdered liver by only about 4-fold while the liver extract increased the activity by 20-fold. Under the conditions of our experiment, it seems that liver extract causes an activation, or perhaps formation, of an enzyme which has some of the properties of a specific cholinesterase, while folic acid increases an enzyme activity which resembles that of a non-specific cholinesterase.

A fatal case of Bartonella Canis treated with penicillin
JOHN EMERSON DAVIS *Pharmacological Laboratory, Univ of Arkansas, Little Rock, Ark.* Since reports of Bartonella Canis infection in splenectomized dogs are quite rare, it seems pertinent to report a severe spontaneous case which showed many of the signs and symptoms of human Oroya Fever. About 90 days after splenectomy had been

performed, one of our dogs appeared to be quite emaciated and was found to have a severe anemia. He had a low grade fever (102.3°), leukocytosis (23000), weakness and pain, a red cell count of 770,000, 2.5 gm % of hemoglobin, a hematocrit of 10.5%, an icteric index of 112, and reticulocytosis (up to 40%). About 75% of the erythrocytes were parasitized by organisms which appeared to be identical with Bartonella Canis. Five cc of blood from this animal was transferred into a second splenectomized dog which, 80 days later, was very anemic (1.9 million RBC) and had parasitized cells, but slowly and spontaneously recovered. Penicillin was given to the original bartonella dog over a 3-day period (10,000 u every 6 hr, I.M.). On the 3rd day of treatment, the blood was cleared of parasites, the icteric index was greatly reduced, and temperature and leukocyte count were normal. By the 4th day, the erythrocyte count had more than doubled, but on the 7th day parasites began to reappear in the blood, and the anemia subsequently became more severe. The dog died in coma, 26 days after his condition had been discovered.

Thiopental hypnosis in rabbits on experimental diets
B. DEBOER *Dept of Pharmacology, St Louis Univ, School of Medicine, St Louis, Mo.* The addition of NaHCO₃ to the diet of rabbits fed whole oats *ad libitum* was accompanied by a shortening of the sleeping time following 2 intravenous injections of 25 mg/kg thiopental an hr apart. Previous information (*Proc Soc Exper Biol & Med* 68, 1948) indicated that the sleeping time of rabbits on a diet of oats for one month was 60% longer than that of rabbits on a diet of Purina rabbit chow. Maintaining these animals upon the experimental diet as long as 20 weeks did not significantly change the effects of thiopental beyond that occurring in 4 to 8 weeks. The addition of NaHCO₃ to the whole grain diet (1% in the daily water supply, which was sufficient to render the urine alkaline) reduced the sleeping time after one week to within 25% of the previous control time. Intravenous injection of 300 mg/kg NaHCO₃ (3 cc of a 10% solution/kg of animal, resulting in approximately 1 gm/animal) preceding the administration of thiopental was without effect the duration of sleep. The effect of diet upon pentobarbital sleeping time was found to be similar. Animals fed rabbit chow averaged 36 and 66 minutes sleeping time after the first and second injections of 25 mg/kg pentobarbital one hr apart. Animals fed whole oats for one month showed only partial recovery during the first hour after the injection and slept an average of 185 minutes after the second injection given at the end of the first hr.

Pentobarbital hypnosis in guinea pigs on ascorbic acid-deficient diet
B. DEBOER and K. O. DEBOER (by invitation) *Dept of Pharmacology, St Louis Univ School of Medicine, St Louis, Mo.* For

58 male and 21 female guinea pigs on a normal diet the sleeping time was 210 minutes when given 25 mg/kg pentobarbital via the peritoneal cavity. The average weight of these animals was 480 grams. After 14 days upon a vitamin C deficient diet the duration of pentobarbital hypnosis was 50% longer than that of controls and after 21 days on the diet 65% longer. The weight of these animals decreased 19% after 14 days and 22% after 21 days on the deficient diet. Returning the animals to a normal diet for 21 days restored the weight to nearly normal and the duration of sleep to within 10% of the previous normal. Ascorbic acid 20 mg/kg given intramuscularly immediately preceding the pentobarbital injection had no apparent effect on the duration of sleep of animals on the deficient diet. Ascorbic acid given 20 or 100 mg/kg 1 hour prior to the injection of the barbiturate in animals 14 days upon the deficient diet had but little effect but in those 21 days upon the diet the sleeping time was 58% above the normal after 20 mg/kg ascorbic acid and 42% above normal after 100 mg/kg ascorbic acid instead of the 65% increase previously noted. In 9 animals on the deficient diet for 14 days a single injection of 100 mg/kg of ascorbic acid was accompanied by a decrease in the duration of sleep (when tested 7 days later) to about 10% above the pre-experimental control sleeping time.

Certain physico-chemical and toxic properties of phenol-camphor preparations. WM B DEICHMANN and T MILLER (by invitation) *Division of Pharmacology, Dept of Physiology and Pharmacology, Albany Medical College, Albany, N Y*. The solubility at 23°C of phenol in mineral oil was found to be 0.1%, in aromatic mineral oil (mineral oil containing traces of eucalyptus and safrol) 0.33%. A 10° increase of temperature raised the solubility about 6 times, to 0.65 and to 1.87%, respectively. Addition of 40 ml of water to 25 ml of a saturated solution of phenol in mineral oil (in a 100 ml separatory funnel having a diameter of 3.88 cm), or to phenol in aromatic mineral oil brought about a redistribution of phenol. At equilibrium, the water phases contained 60 and 50% of phenol respectively. Similar equilibration of a solution of 4.75% phenol and 10.86% camphor in aromatic mineral oil against water led to a phenol concentration in the aqueous phase of 1.026%. Doubling the phenol in the camphor-mineral oil mixture also doubled its concentration in the aqueous phase. The lethal dosages (LD₅₀) of phenol solutions administered as single doses by stomach tube to albino rats were as follows in terms of phenol content: 0.5 gm/kg when given as a preparation of 3.56% phenol in aromatic mineral oil (heated to 34°C), 0.72 gm/kg as a solution of 4.75% phenol in water, and 1.06 gm/kg as a 4.75% solution of phenol and 10.86% camphor in aromatic mineral oil. Immersion of the tails of albino rats in solutions containing

various quantities of phenol continuously up to 8 hours, established the following concentrations that killed approximately 50% of one strain of albino rats: 2.0% phenol in aromatic mineral oil, 4.4% phenol in water, and 7.9% phenol plus 10.86% camphor in aromatic mineral oil. With another strain of albino rats the corresponding LD₅₀ values were 2.7% phenol in aromatic mineral oil, 6.6% phenol in water, and 11.5% phenol plus 10.86% camphor in aromatic mineral oil.

Effects of epinephrine, ephedrine and 1-(m-hydroxyphenyl)-N²-methylethylene diamine (NU-1683) on the coronary blood flow. ADAM B DENISON, JR (by invitation), BEN J LAWRENCE, JR (by invitation) and HAROLD D GREEN *Dept of Physiology and Pharmacology, Bowman Gray School of Medicine of Wake Forest College, Winston-Salem, N C*. Wayne *et al* have reported at this meeting that 1 µgm of epinephrine, 1 mg of ephedrine and 1 mg of NU-1683 produce approximately at 25-50% reduction in flow in the hind leg when injected into the femoral artery. This paper presents the effects of intracoronary artery injections of similar amounts of these drugs upon the coronary blood flow. In dogs anesthetized with pentobarbital, the heart was exposed by removal of the anterior halves of the left 4th and 5th ribs. Heparin plus, in some experiments, chlorazol fast pink, served as anticoagulant. Flow of blood from a carotid into the anterior ramus descendens was measured with a Gregg-Green orifice meter and differential manometer. Epinephrine in the above dosage caused a 50% increase in flow at the end of diastole. The above doses of NU-1683 and ephedrine had no effect. With rise in arterial pressure, which frequently occurred as the drugs reached the systemic circulation, flow increased with all three drugs.

Biosynthesis of radioactive bufagin containing C¹⁴. JOHN DOULL (by invitation), KENNETH P DUBOIS, and E M K GEILING *Dept of Pharmacology, Univ of Chicago, Chicago, Ill*. An investigation of the optimum conditions for the biosynthesis of radioactive bufagin with C¹⁴ was undertaken to obtain labeled bufagin for studying the distribution and fate of this cardiac glycoside in mammals. Since C¹⁴ as carbonate was rapidly excreted in the expired air it was more desirable to feed an organic form of carbon, algae (supplied by Dr W F Libby) grown in the presence of C¹⁴ and containing 406 uc C¹⁴/gm were, therefore, employed. Tropical toads (*Bufo agui*) were used for the biosynthesis. They were kept in an enclosed system through which CO₂-free air was passed allowing the expired CO₂ to be collected in alkali and measured. Two weeks after feeding C¹⁴ the secretion was collected from the parotid glands and the animals were sacrificed for quantitative measurement of the C¹⁴ in the tissues. One toad receiving 50 uc C¹⁴ as radioactive algae contained 8.9% of the administered

dose in the tissues, 11.8% was exhaled as CO_2 and 79.3% was excreted in the urine and feces. Two weeks after 100 μC of C^{14} 29.4% of the original dose was present in the tissues, 17.9% was exhaled as CO_2 and 52.7% was excreted in the urine and feces, mainly in the feces. Of the C^{14} in the tissues the liver contained 16.9%, skeletal muscle and bones 60.0%, small intestine 10.4% and the remainder was rather evenly distributed throughout the other tissues. Radioactive bufagin and epinephrine were obtained from the parotid secretion.

Comparative percutaneous toxicity of 3-mercapto-1,2-propanediol (thioglycerol) and ammonium thioglycolate JOHN H. DRAIZE, ELSIE ALVAREZ (by invitation) and MARIE WOODARD (by invitation) *Division of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D. C.* Ammonium thioglycolate is used extensively in the 'cold-hair wave process'. To a lesser extent thioglycerol is similarly employed. The thioglycolate 'hair waving' procedure is sometimes varied by the application of heat. Ninety-day percutaneous toxicity experiments on the rabbit were undertaken with 7% ammonium thioglycolate (with solution at room temperature and also heated to 47°C), and with a 6% thioglycerol waving solution at room temperature. All waving solutions were adjusted to a $\text{pH } 9.2 \pm 0.1$. Blood examinations, urinary sulfur excretion, and systemic effects in subjects were recorded. Histological examination of tissues were made. Sensitization studies were conducted on the guinea pig. When 4.0 ml/kg/day (a total of 65 doses) of the waving solutions were injected mortalities of 74, 61 and 0% were obtained with ammonium thioglycolate (47°C), ammonium thioglycolate (room temperature) and the thioglycerol respectively. The percentage increase of urinary sulfur reached peak figures of 147, 105 and 83 for ammonium thioglycolate (47°C), ammonium thioglycolate (room temperature) and thioglycerol respectively. Symptoms of poisoning in animals had a rapid onset with all agents and upon discontinuance of treatment recovery was prompt. Extensive skin damage was always associated with serious poisoning. While thioglycerol showed less gross evidence of toxicity it produced a high incidence of sensitization and evidence of pathologic changes in the thyroid gland.

Experimental skin sensitization to sulfonamides and penicillin ROBERT H. DREISBACH *Dept of Pharmacology and Therapeutics, Stanford Univ. School of Medicine, San Francisco, Calif.* Since both sulfonamides and penicillin have been suspected clinically of increasing skin sensitization to each other attempts were made to test this experimentally. Sensitization of the Arthus type was attempted in 12 rabbits by giving 6 weekly subcutaneous injections of 1 cc 0.8% (saturated) sulfanilamide, or 0.06% (saturated)

sulfathiazole, in 0.9% saline solution in separate groups of 6 rabbits each, controlled by similar injections of 0.9% saline. No noticeable swellings or reactions occurred. In order to test possible increased susceptibility to penicillin sensitization in the sulfonamide injected areas of these rabbits, a total of 4 injections of 10,000 units each of crystalline penicillin G in 1 cc of saline solution were made at weekly intervals. Three of 11 rabbits showed a positive Arthus phenomenon, chiefly minor swellings at the injection sites. In our experience, as many as 10 of 12 normal rabbits may show sensitivity reactions to crystalline penicillin G alone. Following the penicillin injections, the same 12 rabbits were given 2 injections at weekly intervals of sulfanilamide or sulfathiazole into the penicillin-sulfonamide areas, in the same manner as before, but no reactions occurred. In another attempt to produce sensitization, cutaneous applications were made of 1% solutions of sulfanilamide or fathiazole in carbitol (known for epidermal penetration) at weekly intervals on separate groups of 6 rabbits each. No sensitization occurred after 8 applications, although the sulfonamides were absorbed (present in urine). According to these methods, therefore, sulfonamide treated skin is not demonstrably sensitized nor does such treatment increase penicillin sensitization.

Inhibitory action of bufagin on carbohydrate oxidation KENNETH P. DUBOIS, JOHN DOULL (by invitation), and E. M. K. GEILING *Dept of Pharmacology, Univ of Chicago, Chicago, Ill.* In connection with studies on the mechanism of action of cardiac glycosides the effect of bufagin on enzymatic reactions was investigated. Bufagin was isolated from the parotid secretion of the tropical toad, *Bufo aqua*, by the method of Jensen and Chen (*J Biol Chem* 87:755, 1930). Since this glycoside has a very low solubility in aqueous media preliminary experiments were carried out by addition of the crystalline compound to achieve saturation of the test system. For further experiments 50% ethanol solutions of bufagin were prepared and further diluted with water for use, appropriate ethanol controls were included. Addition of crystalline bufagin to isotonic brain homogenates resulted in marked inhibition of the oxidation of glucose. The amount of inhibition was consistently greater than 65% for rat, guinea pig and mouse brain homogenates. Further tests showed that a final concentration of $2 \times 10^{-4} \text{ M}$ bufagin resulted in 50% inhibition of the respiration of isotonic brain homogenates. The respiration of brain slices was inhibited to about the same extent as homogenates by similar concentrations of the glycoside. The rate of oxidation of glucose by heart slices from guinea pigs, rats and mice was decreased about 75% by saturating the test system with bufagin. The oxidation of glucose by liver and kidney slices was only

inhibited to the extent of about 15% by saturation of the media with the drug. Bufagin had no effect on anaerobic glycolysis nor on the cytochrome oxidase and succinic dehydrogenase systems.

Bromate distribution in blood. A. L. DUNN (by invitation) and A. R. MCINTYRE, *Dept. of Physiology and Pharmacology, Univ. of Nebraska, College of Medicine, Omaha, Nebr.* The distribution and fate of ingested bromates has not been studied quantitatively previously. In these studies the distribution of bromate in the red cells and serum was determined following the administration of approximately $\frac{1}{2}$ of the delayed M. L. D. per os in the dog. After 75 mg of KBiO_3/kg gram by stomach tube in 100 cc of water followed by another 100 cc of water, blood was collected from a jugular vein at intervals of $\frac{1}{2}$ hour, 1 hour, 2 hours, 4 hours and 24 hours. No anesthetic and no anticoagulant were used. The blood was defibrinated, centrifuged, the serum drawn off, the red cells washed in isotonic saline and hemolyzed, and protein-free filtrates were then prepared. Bromate was determined by the decolorization of Evans blue. The decolorization of this dye has a marked specificity for bromate over the other halates, and was previously described by us (*J. Lab. & Clin. Med.*, in press). This method was modified in such a manner that the bromate was determined spectrophotometrically. The findings indicate that bromate in the above dosage is absorbed rapidly from the gastrointestinal tract and the peak concentration is found in the blood filtrate within one hour following ingestion. The concentration remains at a high level for 3 hours and falls to a negligible amount at 24 hours. No bromate was found in the saline-washed cells.

Renal clearance of streptomycin. A. O. EDISON (by invitation), V. C. JHINER (by invitation) and G. E. BOXER, *Merck Institute for Therapeutic Research and The Research Laboratories of Merck & Co., Inc., Rahway, N. J.* The renal clearance of streptomycin in dogs was obtained by fluorometric determination of the drug in the plasma and urine. The clearance was measured in 5 experiments over 6 equal one-half-hour periods after a single intramuscular injection of the drug. The normal glomerular filtration was determined simultaneously by measuring the renal clearance of thiosulfate ions since the streptomycin interferes with the determination of inulin, mannitol and creatinine. The clearance of streptomycin was on the average 70% below the simultaneously determined glomerular filtration rate. Wide variations in urine flow and the concentration of the drug in the plasma did not influence the clearance, apparently excluding tubular reabsorption. The clearance measured from the rate of disappearance from the plasma and from the calculated volume of distribution of streptomycin was found to agree with the clearance obtained in

the conventional manner from the concentration in plasma and urine and the rate of urine flow. The implications of this finding with respect to the volume of distribution and the manner of excretion are discussed. The clearance calculated from the plasma concentration of the drug was found to be identical for man and dog per unit of surface area.

Biliary excretion and intestinal reabsorption of C^{14} -labeled methadone hydrobromide. L. L. EISENBRANDT, I. A. ABDOU and T. K. ADLER (introduced by H. W. ELLIOTT), *Division of Pharmacology and Experimental Therapeutics, Univ. of California Medical School, San Francisco, Calif.* Using the standard techniques of tracer investigations, C^{14} incorporated into methadone was administered subcutaneously into rats for the purpose of determining methadone excretion via the digestive tract. Elliott, et al. (*J. Pharmacol. & Exper. Therap.* in press) in their distribution studies showed relatively large amounts of radioactive methadone in the liver, intestine and in feces. In the present study the bile duct was cannulated and bile collected for the duration of analgetic effects which usually lasted about 2 hours following 15 mg of methadone. After injection into the left hind leg, the bile became radioactive in approximately 10 minutes. The peak of radioactivity was reached in 60-90 minutes and decreased as analgetic effects diminished. Although much of the radioactive methadone was excreted in the feces, reabsorption in the small intestine appeared likely. Radioactive bile collected from one animal (donor), and 1 ml was then injected into the duodenum of a second rat which was also cannulated for bile collection. Samples of bile from the recipient became radioactive in about 10 minutes, and this animal showed definite signs of analgesia. Apparently, radioactive methadone was excreted through the intestinal route and, in addition, portions were reabsorbed and distributed throughout the body in sufficient amounts to produce analgesia.

Respiration of human brain slices and the effects of morphine and methadone on oxygen uptake. H. W. ELLIOTT (by invitation), V. C. SUTHERLAND and E. B. BOLDREY, *Divisions of Pharmacology and Experimental Therapeutics and of Neurological Surgery, Univ. of California Medical School, San Francisco, Calif.* Samples of cerebral cortex were obtained from patients undergoing surgical removal of various types of brain tumors. The tissue was immediately iced, transferred to a cold box and prepared for respiration studies. Pieces of cortex were isolated with scissors, sliced freehand with a razor and template, weighed and placed in Warburg flasks. The data obtained from 7 human brains studied to date follow. The QO_2 of human cerebral cortex slices in glucose-Ringer- PO_4 , 30 minutes after equilibration at 37°C , was approximately 1.0 on a wet weight

basis. One hundred fifty minutes later the values for oxygen uptake had fallen 20–30%. For purposes of comparison 30-minute QO_2 's for dog and rat cortex were 1.7 and 2.3, respectively. These species differences are to be expected because of the inverse relationships between metabolic rate and body size. Human cortex slices exhibited a striking difference in behavior from rat cortex slices when O_2 uptake was determined in Ringer- PO_4 containing no glucose. Rat cortex QO_2 's fall very rapidly in the absence of substrate but human cortex respiration is not affected. QO_2 's were just as high and as well maintained over a 3-hour period in unfortified Ringer- PO_4 as when glucose was added. The nature of the substrate apparently stored in human cortical tissue is as yet undetermined. To some vessels morphine and methadone were added after a 90-minute control period. The drug levels studied were 1) 0.002M morphine HCl, 2) 0.0005M methadone HCl and 3) 0.002M methadone HCl. The O_2 uptake of both rat and human cerebral cortex slices in glucose-Ringer- PO_4 was not affected by 1), stimulated by 2) and strongly inhibited by 3). The respiration of human brain slices in Ringer- PO_4 without added glucose was not affected by 1) and inhibited by 2). A comparison of the findings on rat and human brain indicates that the effects of 0.0005M methadone are on glucose utilization and may be a manifestation of enzyme inhibition rather than stimulation.

Metabolism of isopropyl alcohol by the perfused liver. FRED W. ELLIS, *Department of Pharmacology, Univ. of North Carolina, Chapel Hill, N. C.* Rabbits, fasted for 48 hours, were anesthetized with 40 mg/kg of pentobarbital sodium, intravenously, and prepared for liver perfusion by a modification of the technique of Lundsgaard, Nielsen and Orskov (*Skandinav Arch f Physiol* 73: 296, 1936). Fresh defibrinated, oxygenated rabbit blood diluted to 70 per cent with 0.9 per cent saline was perfused through the *in situ* liver, maintained at body temperature, at the rate of 72 cc/min for a duration of 2 hours. At certain time intervals, the concentrations of sugar, acetone and lactic acid (and alcohol, when present) in the perfusion fluid were determined and liver samples were obtained for glycogen analyses. When isopropyl alcohol was added to the perfusion fluid, there occurred a distinct increase in acetone (a known oxidation product of isopropyl alcohol), as well as a less marked rise in sugar concentration. There was a corresponding decrease in the concentration of isopropyl alcohol. Changes in lactic acid and glycogen values did not seem to be significantly different from the control data. Upon the substitution of ethyl alcohol in the perfusion fluid there was no increase in acetone or sugar, and the rate of disappearance of the alcohol appeared to be somewhat slower than in the case of isopropyl alcohol. Lactic acid concentration remained prac-

tically constant as compared with the progressive decrease in the control and isopropyl alcohol experiments. There was no significant change in liver glycogen.

Photoelectric estimation of 1-carnosine and 1-histidine. G. A. EMERSON and PAUL L. EWING, *Dept. of Pharmacology, Univ. of Texas Medical Branch, Galveston, Texas.* The reaction of Pauly (*Ztschr f physiol Chem* 42: 508–18, 1904) may be adapted to photoelectric colorimetry of carnosine and histidine with certain modifications of the visual method of Koessler and Hanke (*J Biol Chem* 39: 497–519, 1919) proposed by Kuen, Eggleton and others. A Coleman model 11 spectrophotometer was used, at λ 470 m μ . Molar color values of carnosine and carbobenzoxy-carnosine are higher than that of histidine if estimated immediately after diazotization, but approach that of histidine in 30 and 60 minutes, respectively, after which fading is negligible at a room temperature of 32°C, although the apparent spectral transmittance curves still differ somewhat for the secondary minima. Excellent agreement with the Lambert-Beer law obtains with 20–100 α of carnosine or histidine, and the method is suitable for estimations with neutralized Cl_3CCOOH extracts of tissues.

A comparative study of anticonvulsant activities of antiepileptic drugs by electro-shock methods in cats, rats and mice. CHARLES R. ENSOR (by invitation) and GRAHAM CHEN, *Research Laboratories, Parke, Davis and Company, Detroit, Mich.* The anticonvulsant activities of nine antiepileptic drugs were determined with 2 electro-shock procedures, 1) by the increase of electro-convulsive threshold in the cat (Putnam and Merritt) and 2) by the abolition of extensor tonic seizures in rats and mice (Toman, Swinyard and Goodman). The values obtained with the 2 methods agree well in the cat and the mouse in the following order of potency: Dilantin, Mesantoin, Nirvanol, phenobarbital, Mebaral, Phenurone, Carbromal, Epidon and Tridione. In the rat, on the other hand, the protective doses of Mesantoin and phenobarbital were found to be smaller than those of others. The laboratory data are compared with the clinical results for these drugs in the treatment of grand mal epilepsy. They appear to show a fair agreement.

Pharmacological studies of phenacetylurea (Phenurone), an anticonvulsant drug. GUY M. EVERETT (introduced by R. K. RICHARDS), *Dept. of Pharmacology, Abbott Research Laboratories, North Chicago, Ill.* Phenacetylurea (Phenurone) has outstanding anticonvulsant properties against Metrazol and supramaximal shock seizures in mice, rabbits and cats with non-sedative doses (300 mg/kg). The drug also raised convulsive threshold to minimal electroshock seizures in rabbits. The toxicity is low, the LD_{50} by IP or oral administration being 2

to 3 gm/kg Slight ataxia appears at 400 mg/kg The EEG in unanesthetized cats and rabbits remained unchanged with doses up to 1 gm/kg Higher doses produce high voltage slow wave activity The duration of anticonvulsant action in mice is 3 to 5 hours The duration remained unchanged in double nephrectomized mice, but was significantly prolonged (20 hours) by CCl_4 liver damage and hepatectomy In man Phenurone causes signs of stimulation more often than sedation The drug has been found effective in some resistant grand and petit mal cases and is particularly useful in psychomotor epilepsy

Comparative effects of adenosine, isoguanosine and related compounds on smooth muscle PAUL L EWING, FRITZ SCHLENK and G A EMERSON *Dept of Pharmacology, Univ of Texas Medical Branch, Galveston, Texas, and Dept of Bacteriology, Iowa State College, Ames, Iowa* Isoguanosine (2-oxyadenosine) was found to be about 3 times as active as adenosine in depressing the anesthetized rabbit's blood pressure after intravenous injection, in inhibiting rhythmic contractions of isolated rabbit or hamster intestine, and in stimulating the hamster uterus On the isolated guinea pig uterus, isoguanosine was 60-100 times as effective a stimulant as adenosine The related pyrimidines, cytosine and isocytosine, while much less active than adenosine, show the expected biochemorphic relationships Although *in vitro* studies have demonstrated the production of glutamine and inosinic acid from ATP, glutamate and ammonia with tissue enzymes, we were unable to find any gross evidence of the reverse process, i e, the production of active amounts of adenylic acid from a combination of inosinic acid and either glutamine or asparagine as amino donors

Action of some enzyme inhibitors on the activity of the isolated intestine A FARAH, R ANGEL (by invitation) and T C WEST (by invitation) *Dept of Pharmacology, School of Medicine, Univ of Washington, Seattle, Wash* Isolated intestinal strips of the rabbit were placed in glucose-free Tyrode solution After 30-60 minutes the intestinal strip showed a marked reduction in the height of spontaneous contractions and usually a loss in tone In confirmation of results of previous workers, the addition of glucose, mannose, acetate, pyruvate and a number of fatty acids produced a recovery of the spontaneous contractions The enzyme inhibitors malonic acid, p-chloromercuric benzoate, sodium fluoroacetate, dinitrophenol, propionic acid, sodium cyanide and sodium azide were studied The effect of some of these inhibitors was dependent on the type of substrate employed The results will be presented and discussed in the light of our knowledge of the intermediary metabolism of carbohydrates and fatty acids

Method for determining hydroquinone excretion

in the urine DAVID W FASSETT *Laboratory of Industrial Medicine, Eastman Kodak Company, Rochester, N Y* Because of the current interest in hydroquinone as an antioxidant for use in foods, and in the possible use of sodium gentisate in rheumatic fever, a study has been made of the excretion of hydroquinone in the urine of man and animals The lack of specificity and sensitivity of available methods has been overcome by a modification of the procedure described by Sterner, Oglesby and Anderson for quinone vapors (*J Indust Hyg & Toxicol* 29 60, 1947) The intense color formed by the simple addition of hydroquinone to an alkaline phloroglucinol solution has a characteristic absorption spectrum with two maxima at 420 and at 515 millimicrons Catechol gives an equally intense but entirely different color, and resorcinol and phenol give no color under the same circumstances Conjugated hydroquinone is estimated after hydrolysis of the urine with normal sulfuric acid Amount of less than one microgram can be detected Hydroquinone in both free and conjugated form (mostly the latter) is normally present in the urine of men, rats, guinea pigs, and cats About 20-50 mg/24 hours is estimated to be a normal value for man, although this will vary with the type of diet After ingestion of hydroquinone by mouth or by injection, large amounts are excreted in the conjugated form starting in an hour or two, indicating that the body eliminates hydroquinone rapidly Compounds such as nor-dihydroguaiaretic acid also give a characteristic color with alkaline phloroglucinol but are less rapidly excreted

Coenzyme I—Quinine relationships in bacterial growth and metabolism R M FEATHERSTONE and J R PORTER (by invitation) *Depts of Pharmacology and Bacteriology, College of Medicine, State Univ of Iowa, Iowa City, Iowa* It has been reported by others that coenzyme I will reverse the inhibitory effects which quinine has on the metabolism of *Escherichia coli* In the work to be reported, turbidimetric measurements of growth, methylene blue reduction studies, experiments using standard manometric techniques, and microbiological assays for coenzyme I have been utilized in an investigation of quinine-coenzyme I relationships as they pertain to the growth and metabolism of several bacterial species The results indicate that the apparent coenzyme reversal of quinine inhibition of methylene blue reduction by bacterial cells may be due to an oxidation of the coenzyme molecule This oxidation is not inhibited by the concentrations of quinine used and it proceeds independently of the retarded glucose oxidation It has also been shown that numerous other growth factors fail to reverse the quinine inhibition of growth or respiration of the several bacterial species studied

Local anesthetic activity of a series of aminoalkoxy isoquinolines EDWIN J FELLOWS and EDWARD MACKO (by invitation) *Dept of Pharmacology, Temple Univ School of Medicine, Philadelphia, Penna* The following compounds were tested for local anesthetic activity after topical application to rabbits' eyes 1-(beta-Dimethylaminoethoxy)-isoquinoline Monohydrochloride (I), 1-(beta-dimethylaminoethoxy)-3-propylisoquinoline Monohydrochloride (II), 1-(beta-Dimethylaminoethoxy)-3-butylisoquinoline Monohydrochloride (III), 1-(beta-Diethylaminoethoxy)-3-methylisoquinoline Monohydrochloride (IV), 1-(beta-Di-n-butylaminoethoxy)-isoquinoline Monohydrochloride (V), 1-(beta-N-piperidylethoxy)-3-methylisoquinoline Monohydrochloride (VI), 1-(beta-N-piperidylethoxy)-3-ethylisoquinoline Monohydrochloride (VII), 1-(3-Diethylaminopropoxy)-3-ethylisoquinoline Monohydrochloride (VIII), 1-(beta-Benzylaminoethoxy)-3-ethylisoquinoline Monohydrochloride (IX) All of the present derivatives exhibited anesthetic activity Derivatives nos II, IV, VI, VII, VIII and IX produced anesthesia for periods of 26 to 94 minutes in 0.01% concentration However, no III was outstanding in that an average of 75 minutes anesthesia was noted after application of 0.001% solution In comparative studies anesthesia was noted for a period of 18 minutes after 1.0% cocaine and for an average duration of 69 minutes after 0.01% dibucaine hydrochloride

Influences of progesterone and testosterone on reactivity of rabbit myometrium to oxytocin and vasopressin PAUL P C FENG (by invitation) and R A WOODBURY *Division of Pharmacology, Univ of Tennessee, Memphis, Tenn* Investigations were conducted on isolated uterine strips from rabbits, varying in age from 3 months to 3 years, with or without previous pregnancies Twenty-one rabbits were sensitized by injecting 0.01-0.02 mg of stilbestrol daily for a period of 7 days (Control studies showed that such treatment produced full sensitization of the myometrium to oxytocin and vasopressin) After sensitization 1 uterine horn was removed to test its reactivity to oxytocin and vasopressin These results were then compared with the reactivity of the remaining horn removed after 5 days additional treatment with various combinations of stilbestrol and either progesterone or testosterone In 8 rabbits, a stilbestrol/progesterone ratio of 1:20 to 1:100 decreased the reactivity of sensitized myometrium to oxytocin and vasopressin to similar degrees varying from five-fold to one hundred and fifty-fold In 13 rabbits, a stilbestrol/testosterone ratio of 1:100 to 1:400 decreased the reactivity to oxytocin and vasopressin from 2-fold to 330-fold However, testosterone decreased to a greater extent the reactivity to vasopressin in 9 of the 13 rabbits and to the

same extent in 3 of the remaining 4 In stilbestrol-sensitized and non-sensitized rabbits, the oxytocic activity of vasopressin was roughly 20 times that as specified in the current N N R These results are comparable with those reported by Bachinski and Allmark on normal rabbits (*J Am Pharmacol Assoc* 34:73, 1947)

Action of 4-amino, N 10-methyl, pteroylglutamic acid in mice, rats, and dogs F C FERGUSON, JR (by invitation), J B THIERSCH (by invitation), and F S PHILIPS *Dept of Pharmacology, Cornell Univ Medical College, and Division of Experimental Chemotherapy, Sloan-Kettering Institute for Cancer Research, New York City* The intraperitoneal LD_{50} of 4-amino, N 10-methyl, pteroylglutamic acid in mice was 94 ± 8.8 mg/kg in a single dose and 1.94 ± 0.30 mg/kg/day given for 5 successive days, and in rats, 12.6 mg/kg acutely (with much variation) and 1.11 ± 0.34 mg/kg/day for 5 successive days Orally in rats the acute LD_{50} was 180 ± 45 mg/kg Signs of intoxication included weight loss, anorexia, diarrhea, dehydration, and weakness, complicated by secondary infections, with death after 3 days Rats sacrificed within 72 hours after large acute doses and after chronic doses given for 60 days, showed lesions in the bone marrow and intestines, the lymphoid tissues remaining relatively unaffected The intestinal mucosa showed hyperemia, edema, desquamation and leucocytic infiltration The marrow became fluid and hypocellular in the myeloid and erythroid elements The blood showed progressive normochromic normocytic anemia, reticulocytopenia, and leucopenia Dogs receiving various doses were followed with serial blood counts and sternal marrow aspirations The course of intoxication and the lesions seen were similar to those in rats In addition, megaloblasts appeared in the marrow, the lymphoid tissues appeared reduced and ulcerative colitis was prominent

Comparison of the chronic toxicity of alpha, beta and gamma isomers of benzene hexachloride O G FITZHUGH, A A NELSON and OMA L HOLLAND (by invitation) *Division of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D C* Following our observation that technical grade benzene hexachloride was more toxic than could be accounted for by the gamma content, a chronic experiment on the individual isomers was started Albino rats, 21 days old, 20 to a group, were fed dosages of 10, 100 and 800 ppm of the alpha, beta and gamma isomers in a stock diet for their lifetime Additional dosage levels of 5, 50 and 1600 ppm gamma and 50 ppm alpha were used Results showed that the beta isomer was more than twice as toxic as the gamma and that the alpha isomer was of the same order of toxicity as the gamma All rats receiving the 800 ppm beta isomer died within the first 10 weeks of

the experiment, whereas some of those on 1600 ppm gamma survived for more than a year. Retardation in growth occurred at the 800 ppm dosage level for each isomer. Lower dosage levels did not affect growth. Rats on the high dosages of the gamma isomer had severe convulsions. At 100 ppm all isomers produced slight but distinct histological changes in the liver, and, with the alpha and gamma, in the kidney also. The beta affected the liver in a greater degree at a given level. The gamma and alpha isomers produced no damage to the liver or kidney at the 10 ppm and the beta at this level showed a questionable injury to the liver.

Mercury content of human tissues from routine autopsy material. ROBERT B. FORNEY (introduced by H. R. HULPIEU) and R. N. HARGER, *Dept. of Biochemistry and Pharmacology, Indiana Univ. School of Medicine, Indianapolis, Ind.* Using the method of Laug and Nelson (*J. Assoc. Off. Agr. Chem.* 25:390, 1942) mercury analyses were run on kidneys and livers from 117 consecutive autopsies. These comprised group A, 92 persons with no known mercury medication, and group B, 25 persons with a history of the administration of mercury diuretics. In group A the frequency distribution of mercury concentration expressed as mg % of the fresh organ was, kidneys: 9, none (< 0.01 mg %), 20, 0.01-0.10, 28, 0.11-0.50, 22, 0.51-1.00, and 11, 1.01-12.7; and liver: 18, none, 37, 0.01-0.10, 26, 0.11-0.50, 5, 0.51-1.00, and 3, 1.01-1.72. Concentrations of mercury above 0.1 mg % were found in 67.5% of the kidneys and 34.5% of the livers. In group B the distribution of mercury levels was, kidney: 1, 0.94, 12, 1.1-5.0, 6, 5.1-10.0, 3, 12.0-15.0, 1, 21.7, and 1, 27.5; and liver: 15, 0.11-0.50, 4, 0.51-1.00, and 3, 1.1-2.5. In all of the cases in group A and in most of the cases in group B there was no microscopic evidence of the pathological changes associated with acute mercury poisoning, although a few of group B showed mild changes. In 24 of the cases separate analyses were run on the cortex and medulla of the kidney. In 22 of them the cortex/medulla ratios varied from 1.1 to 6.8. The highest level of mercury was found in the kidney with the liver next, followed by the spleen.

Respiration apparatus for rabbits and its use in the study of piperidine analgesics. R. H. K. FOSTER and B. DEBOER, *Dept. of Pharmacology, St. Louis University School of Medicine, St. Louis, Mo.* The apparatus, which eliminates the use of respiratory valves, consists of a closed two-compartment rabbit holder, a 40 gallon air reservoir with a blower for introducing fresh air, 2 damped float recorders and an air circulating fan. A perforated rubber diaphragm fitting snugly around the rabbit's neck separates the two compartments of the rabbit holder. The larger compartment, holding the rabbit's body, is connected to one float re-

corder for registering rate and depth of respiration, the smaller, holding the rabbit's head, is connected in turn to the soda lime container, the air reservoir, the small air circulating fan and thence back to the head compartment. An outlet from the air reservoir is connected through a fine capillary to the second float recorder for recording oxygen consumption. The damping effect of the capillary prevents oscillations due to breathing and results in practically a smooth line. Morphine sulfate and dl- α -1,3-dimethyl-4,4-phenylpropionoxypiperidine hydrochloride (Nu-1196) were injected in doses of 2 and 5 mg/kg. Both drugs produced about equally a marked decrease in rate and minute volume but tidal volume and oxygen consumption showed no significant changes from the control period. The onset was slightly faster with Nu-1196 and recovery definitely faster. Other members of the series are under investigation.

Effects of posterior pituitary hormones on carbohydrate metabolism. ALEXANDER MACL. FRASER, *Dept. of Pharmacology, McGill University, Montreal, Canada.* The hyperglycemic action of pituitary extract is well known, it has been attributed to the oxytocic hormone in the case of the dog. Hyperglycemia following administration of glucose or adrenaline decreases blood inorganic phosphate, due to increased insulin secretion, but workers have shown that pituitary extract increases blood inorganic phosphate, and that pitressin antagonizes the fall in inorganic phosphate caused by insulin. In the present work, the effects of highly purified preparations of the oxytocic and pressor hormones on the sugar and inorganic phosphate of the blood were studied in dogs. The results show a drop in phosphate following oxytocic hormone, and a rise following the pressor hormone. Blood sugar rose after injection of each hormone. The hyperglycemic action of the pressor preparation cannot be accounted for, quantitatively or qualitatively, by its contamination with oxytocic hormone, therefore a hyperglycemic action is attributed to the pressor hormone. It appears likely that the decrease in plasma phosphate after the oxytocic hormone is due to increased insulin secretion, which is caused, in turn, by the hyperglycemia. Consideration of the doses of the pressor hormone required to produce the above changes, leads to the suggestion that the increases in phosphate and sugar following administration of this hormone are due to tissue anoxia, which results from the vasoconstriction, anoxia is known to produce such changes. Hyperglycemic doses of the oxytocic hormone are within a more physiological range.

Rate of disappearance of isomers of benzene hexachloride from fat depots in rats. JOHN P. FRAWLEY (by invitation) and O. GARTH FITZHUGH, *Division of Pharmacology, Food and Drug*

Administration, Federal Security Agency, Washington, D C Previous experiments in this laboratory have shown that the chronic storage of the beta isomer of benzene hexachloride was considerably greater than that of the other isomers and that the principal storage took place in fat tissue. Data are presented here to show the various rates of disappearance of the isomers from the fat tissue. Rats were fed the isomers of benzene hexachloride at 100 ppm and 500 ppm until the maximum storage level was reached. Fat tissues from both sexes on the isomers were analyzed at the maximum level of storage, and repeatedly thereafter until the level fell below the sensitivity of the method of analysis. The method was based on the conversion of the benzene hexachloride to 1,2,4-trichlorobenzene and the estimation of this compound by means of the ultraviolet spectrophotometer. The results obtained from the female rats are summarized in the following table.

Disappearance of Isomers of BHC in Female Rats

Concentration Original Diet	Weeks Control Diet	Conc of Isomers (Mg/g)			
		alpha	beta	gamma	delta
ppm 100	0	0 177	1 014	0 102	0 128
	1	0 142	0 860	0	0
	2	0	0 837		
500	0	1 180	No	0 281	0 376
	1	0 281	survivals	0 039	0 188
	2	0 158		0	0

The disappearance of the isomers from fat tissue of male rats is accomplished sooner than in female rats.

Effects of indophenols on glycolysis JAMES A. FREEK (introduced by G. L. GEMMILL) *Dept of Pharmacology, Univ of Virginia Medical School, Charlottesville, Va* A study was made of the effect of some indophenols on glycolysis in frog muscle extracts. The rate of glycolysis was determined by the liberation of carbon dioxide from a bicarbonate buffered solution in a Warburg vessel. The following compounds completely inhibited glycolysis at 0.001 to 0.008 M: 2,6-dibromo-3'-carboxyindophenol, 2,6-dichloro-3'-chloroindophenol, 2,6-dibromoindophenol and 2,6-dichloro-3'-methylindophenol. The following compounds partially inhibited at 0.008 to 0.03 M: 2,6-dichloroindophenol, 2,6-dibromo-3'-methoxyindophenol, 2,6-dibromo-2'-methyl-5'-isopropylindophenol, 3'-methyl-6'-isopropylindophenol, 2'-methyl-5'-isopropylindophenol, 3'-methylindophenol, 2'-methylindophenol, 2,6-dibromo-3'-methylindophenol, 2,6-dibromo-3'-methylindophenol, indophenol, and 3'-naphtholsulfonate. 2,6-Dichloroindophenol, 2,6-dibromo-3'-carboxyindophenol and 3-chloroindophenol at 0.0001 M increased the amount of carbon dioxide production.

This activating effect was dependent on the normal activity and reducing capacity of the extract. The inhibition produced by 2,6-dibromo-3'-carboxyindophenol and 3'-naphtholsulfonate was not reversed by glutathione or cysteine. Inhibition by 2,6-dibromo-3'-carboxyindophenol was reversed in the presence of added ATP. There was no quantitative relationship between inhibition and the oxidation-reduction potentials of the indophenols.

Responses to epinephrine and norepinephrine after dibenamine WALTER A. FREYBURGER (by invitation), LUIS R. CAPO (by invitation), and GORDON K. MOE *Dept of Pharmacology, Univ of Michigan, Ann Arbor, Mich* In the intact dog dibenamine 'reverses' the pressor action of epinephrine in doses which depress but do not abolish or reverse the pressor action of norepinephrine. 'Reversal' of epinephrine is thought to represent unmasking of its vasodilator activity. Since a depressor action of epinephrine is rarely apparent in the pithed animal, one might expect that the pressor effects of the two amines would be depressed to an equal degree by dibenamine in this preparation. This was found to be the case. In a series of intact anesthetized dogs dibenamine, in a dose which reduced the maximum response to epinephrine to a pressure rise of 5 mm Hg followed by a fall, reduced the pressor action of norepinephrine by only 50%. In the pithed cat, pressor responses to the two amines were reduced to exactly the same degree by dibenamine. If the vasodilator action of epinephrine depends upon an intact autonomic nerve supply, interruption of such pathways by tetraethylammonium (TEA) should abolish vasodilator responses. TEA was found to abolish the pressure fall normally observed after small doses of epinephrine. The depressor response to epinephrine which occurs following dibenamine, however, was only occasionally prevented by TEA. Although the difference may be only quantitative, there is a possibility that the vasodilator effect of epinephrine following a reversing agent differs from the normal vasodilator effect demonstrable with small doses.

Paper chromatography of flavonoid pigments II. Separation and quantitative estimation of rutin and quercetin. THOMAS B. GAGE and SIMON H. WENDER (introduced by ARTHUR A. HELLBaum) *Chemistry Dept, Univ of Oklahoma, Norman, Okla* The qualitative separation and identification of micro quantities of 11 flavonoid pigments by paper partition chromatography has been previously reported by the authors (*Science* in press). A micro method of quantitatively estimating the amounts of certain flavonoid pigments initially present in a mixture has now been developed. Mixtures of rutin and quercetin have been separated and quantitatively determined.

by the following procedure Whatman No 1 filter paper strips, 2.5×50 cm were spotted by means of a micro pipette with 5-10 μ l of a solution containing 10-40 μ g of each pigment. The strips were chromatographed in a one-dimensional apparatus with such solvent combinations as ethyl acetate-water or n-butanol-acetic acid-water (40-10-50 vol %) Blank strips were treated similarly in order to provide solvent blanks for the preparation of absorption spectra curves. The strips were air-dried, and the pigment zones located by their fluorescence in ultraviolet light. The isolated pigment zones and the corresponding areas of the blank strip were cut out and the paper extracted in closed containers with solvents such as 5 cc of ethanol containing 0.02 cc of concentrated HCl. The Beckman model DU quartz spectrophotometer, fitted with micro absorption cells, was used for obtaining spectral data. Rutin and quercetin were identified by the shape of their characteristic ultraviolet absorption spectra curves and the amount recovered was calculated from their extinction values at 362.5 and 375 $m\mu$ respectively. Further studies are in progress with combinations of 2 and 3 flavonoid pigments often found associated together in natural products.

Studies on furan compounds toxicity and pharmacological action of furfuryl alcohols
JOHN E. GAJEWSKI and WILLIAM R. ALSDORF (introduced by C. H. HINE) *Naval Medical Research Institute, Bethesda, Md.* Upon oral administration of a 2.0% aqueous solution of furfuryl alcohol, the LD-50 for white rats is 275 mgm per kilo. Administered intravenously as a 10% aqueous solution to rabbits, the LD-50 is 650 mgm per kilo. The marked difference between oral and intravenous toxicity can probably be explained on the basis of destruction of furfuryl alcohol by the gastric juice, since this substance is very unstable in an acid medium. This difference does not exist with the more stable hydrogenated analog, tetrahydro-furfuryl alcohol, (oral LD-50 for white rats, 4500 mgm per kilo, intravenous LD-50 for rabbits, 725 mgm per kilo). Either alcohol chronically administered to rats in the drinking water over a period of 20 days results in marked anorexia and weight loss. Intravenous injection of either alcohol into rabbits produces a flaccid paralysis, which becomes permanent with large doses. Recovery from smaller doses is complete in a period of about thirty minutes. On smooth muscle furfuryl alcohol exerts a slight antispasmodic effect. In dogs, upon intravenous injection, the depression of respiration is not accompanied by any changes in blood pressure until doses near the lethal are given. In all species death results from respiratory paralysis.

Metabolism of radioactive nicotine A. GANZ (introduced by F. E. KELSEY) *Dept of Pharmacology, University of Chicago, Chicago, Ill.* The

biosynthesis of C^{14} labeled radioactive nicotine has been reported by Geiling, Kelsey, McIntosh and Ganz in *Science* 108: 558, 1948. Using radioactive nicotine with a specific activity of 57,000/min/mg, rats and mice were injected intravenously and the distribution of the drug among the various organs and body fluids was studied. Distribution and fixation studies on the isolated heart of the guinea pig were also carried out with simultaneous analyses being made of the perfusion fluid. The relationships between the tissue data, the perfusate analyses and the kymograph records were investigated.

Effects of naphthoquinones and related compounds on glycolysis CHALMERS L. GEMMILL *Dept of Pharmacology, University of Virginia Medical School, Charlottesville, Va.* The study of the action of some of the naphthoquinones and related compounds on muscle glycolysis reported last year (*Federation Proc.* 7: 220, 1948) has been extended. A detailed investigation was made of the effects of various concentrations of sodium 1,2-naphthoquinone-4-sulfonate on glycolysis of glycogen to lactic acid in muscle extracts of frogs. With small amounts (1×10^{-4} Molar) of this compound a slight stimulation of glycolysis was observed, while larger amounts caused a progressive decrease in glycolysis, with practically complete inhibition occurring at concentrations of 6×10^{-4} Molar. Several of the compounds having Vitamin K activity gave partial inhibition of glycolysis in amounts of 0.002 Molar or less. These compounds were 2-methyl-1,4-naphthoquinone (Eastman), sodium-2-methyl-1,4-naphthohydroquinone diphosphate (Parke Davis Co.) and 2-methyl-4-amino-1-naphthol hydrochloride. 2-methyl-3-hydroxy-1,4-naphthoquinone (Phthiocol) gave partial inhibition of glycolysis in a concentration of 0.001 Molar. A polarographic examination (carried out by Mr. J. G. Hilton) of the sodium 1,2-naphthoquinone-4-sulfonate in the muscle enzyme solution revealed that from 80 to 90% of this compound is destroyed or bound in its reaction with the glycolytic mechanisms.

Chemotherapeutic efficacy of nitrofurazone (furacin) in experimental trypanosomiasis of the mouse N. J. GIARMAN (by invitation), B. A. RUBIN and E. L. MCCAWLEY *Laboratories of Pharmacology and Bacteriology, Yale Univ. School of Medicine, New Haven, Conn.* Single oral or subcutaneous doses of 500 mg of nitrofurazone per kg of body weight were capable of curing mice which had been given a massive, lethal infection of *Trypanosoma equiperdum* (one million organisms injected intra-abdominally). There were no therapeutic failures at this dose level in 120 mice, some of which were observed for 180 days after infection. The average survival time of infected but un-

treated animals was 84 hours. The chemotherapeutic index for nitrofurazone, calculated on the basis of $LD_{50}/ED_{95} \times 100$, is 107 when the drug is administered orally, and 117 when it is given subcutaneously. These indices compare favorably with those of such trypanocidal antimonials as fuadin and stibenyl, which were calculated in the same manner from the data of Chen *et al.* (*J Infect Dis* 76: 144, 1945) on intramuscular therapy of trypanosomiasis, as 87 and 143 respectively. When the infecting inoculum was increased to 10 million organisms, the dose of 500 mg/kg was still capable of curing 100% of the experimental animals. When treatment was withheld for 60 hours, at which time the first inoculated control animal had succumbed to the infection, the dose of 500 mg/kg subcutaneously cured 50% of the animals. Nitrofurazone has a low order of toxicity. Doses of the drug in the magnitude of 30 to 50 mg/kg given intravenously to nembutalized dogs and cats failed to produce any profound toxic changes in the blood pressure, EKG, EEG, or respiration. The LD_{50} for nitrofurazone administered orally to the mouse is 737 mg/kg, leaving a convenient margin of safety from the effective dose of 500 mg/kg.

Pharmacological studies on actidione. ANDRES GOTH and FABIAN J. ROBINSON (by invitation). *Dept of Physiology and Pharmacology, Southwestern Medical College, Dallas, Texas.* The antibiotic actidione has been shown to be markedly inhibitory for certain pathogenic fungi (Whiffen, A. J., *J Bact*, 56: 283). It also showed a marked species variation in its toxicity for mammals. Despite its toxicity it seemed of interest to study blood levels of the antibiotic in several species of animals. A solution of crystalline actidione was injected intraperitoneally into rats, dogs, and guinea pigs. The citrated plasma of these animals was tested by a serial dilution method in tryptose phosphate broth. The test organism was *Saccharomyces pastorianus*, ATCC 2366, and the inoculum was adjusted to give a final concentration of 1:250 of a 24 hour culture. In the rat the injection of 1 to 10 mg/kg of actidione was followed in 30 minutes by plasma levels of 5-20 dilution units per cc. The inhibitory activity decreased in 90 minutes but was still demonstrable. In the dog and the guinea pig the results were essentially the same as in the rat. These data indicate that actidione is rapidly absorbed from the intraperitoneal site in the rat, dog, and guinea pig and is demonstrable in plasma for at least 90 minutes. Since inhibitory blood levels can be obtained following the injection of sublethal doses of actidione, the possibility exists that the compound may exert a chemotherapeutic effect against susceptible pathogenic fungi in experimental animals and man.

Modified ultraviolet spectrophotometric method for quantitative determination of barbiturates

THELMA C. GOULD, ELIZABETH L. MAIO, and KARL P. BOWMAN (introduced by CHARLES H. HINE). *Divisions of Pharmacology and Experimental Therapeutics and of Psychiatry, Univ of California Medical School and Langley Porter Clinic, State Dept of Mental Hygiene, San Francisco, Calif.* Diethyl ether rather than chloroform was used to remove the barbiturate from the sample of blood. A semi-micro, continuous extractor permits direct extraction of from 0.5-5 ml sera. This procedure is less time-consuming than previous methods and has simplifications regarding apparatus, procedure, and glassware. By extraction at the normal pH range of serum, all sulfonamides thus far tested, which may contribute to ultraviolet absorption, are eliminated. The major problem arising in spectrophotometric determination of barbiturates is the ultraviolet absorption by other extractable materials present in blood sera. In experimental work, the optical density of sera can be determined prior to administration of barbiturate, and correction made. In forensic toxicology, however, where no blank specimen is available, this is not possible. To account for this possible error, the optical density of normal human sera was determined in 100 samples. This variation was from 0.040 to more than 0.200 at a wave length of 245 mμ, with the majority of sera falling within the range of optical density of 0.100-0.150, with a mean of 0.130. When this value is used as a blank reading in barbiturate-containing serum, the error involved would probably not exceed 0.5 mg%. The pH should be carefully adjusted between 9.5 and 10.0 when reading optical density, to detect the typical lactam-barbiturate curve. This is not obtained otherwise, and its maximum may be obscured by the serum blank.

Synergistic chemotherapeutic effect of penicillin and aurothioglucose (Solganal). ARNOLD GRANDAGE, LEILA DIAMOND, MARVIN ROSENKRANTZ, JEANNE H. CHASE, RICHARD TISLOW and ERWIN SCHWENK (introduced by H. B. Haag). *Biological Research Labs, Schering Corporation, Bloomfield, N. J.* The chemotherapeutic effects of aurothioglucose (Solganal) and penicillin were studied in albino mice infected with *Borrelia novyi* (culture obtained through the courtesy of Dr. R. J. Schmitzer, Hoffmann-La Roche, Nutley, New Jersey). A shortened assay procedure similar to that described by Buck, Farr and Schmitzer (*Science* 104: 307, 1946) was used. Mice inoculated intraperitoneally with standardized dilutions of blood in Tyrode solution from mice carrying infection of *Borrelia novyi* were treated in separate experiments with graded doses of penicillin or aurothioglucose and checked for clearance of the blood from *Borrelia novyi* at the end of 24 hours. A satisfactory dose response relationship was obtained with both drugs. Also a satisfactory dose

response relationship between graded inocula and clearance was found using 1 dose of aurothioglucose or penicillin. On the basis of these preliminary experiments 4 short-term experiments, each with groups of 6 animals per dose level, were run to determine the effect of combined treatment with aurothioglucose and penicillin. Aurothioglucose was injected intraperitoneally 4 hours before and crystalline sodium penicillin G immediately after infection. The results of each of the 4 experiments revealed a synergism of the 2 drugs. According to the combined data 8 U/gm of penicillin cleared 37% and 0.05 mg/gm of aurothioglucose 9% of the mice, whereas a combined treatment with the 2 drugs at these dose levels resulted in a 75% clearance. Similarly 8 U/gm penicillin and 0.09 mg/gm aurothioglucose cleared 37% and 13% respectively and the 2 drugs in combination 93% of the animals. These data indicate that combined therapy in this dosage range produced more than an additive effect.

Toxicity of ozone under simulated industrial conditions. M. G. GRAY, *Labys of Arthur D Little, Inc., Cambridge, Mass.* The use of ozone as an 'air-purifier' in garages has directed attention to the limited data regarding its actual toxicity in concentrations of the order of 1 ppm. An experimental study is reported in which rats, mice and rabbits were exposed to a) ozone, b) to exhaust fumes from an internal combustion engine and c) to an atmosphere combining a) and b). This was done in a gas chamber designed to simulate conditions in a service garage. The duration of exposure was equivalent for the species used to more than 1 year of average working time for garage employees. Neither ozone (1 ppm), motor exhaust fumes (containing 50 ppm carbon monoxide) or a combination of these produced significant changes in the physical condition, nutritional status or gross findings at autopsy. No evidence was obtained to support claims that ozone decreases the toxicity of carbon monoxide. The study was carried out in a gas chamber designed to permit the blending of several gases with normal atmospheres while maintaining constant physical conditions. By use of interchangeable panels, the size of the chamber can be altered to suit the requirements of several kinds of experimental work.

Xanthine studies 1) effects of aminophyllin, 1,3 diethyl 8 bromoxanthine and 1,3 dimethyl 8 chloroxanthine on cardiac output. D. M. GREEN, W. C. BRIDGES, A. D. JOHNSON, J. H. LEHMANN, F. GRAY, and L. FIELD (all by invitation), *School of Medicine, Univ of Washington, Seattle, Wash.* 1,3-diethyl-8-bromoxanthine and 1,3-dimethyl-8-chloroxanthine have been compared with aminophyllin as to effect on cardiac output. The subjects consisted of 45 patients with myocardial insufficiency. Output was measured by the Fick

method. Total of output determinations numbered 236, of which 118 followed intravenous administration of a test drug. Aminophyllin was the most active compound and produced an average increase in output of 12% in doses of 250 mg. 1,3-diethyl-8-bromoxanthine was qualitatively similar to aminophyllin but the effect on output was approximately $\frac{1}{3}$ as intense. 1,3-dimethyl-8-chloroxanthine was followed by a small net decrease. The actual effect on output was probably greater than indicated by comparison of post-injection with pre-injection values, for a fall in output of approximately 10% was observed when repeated determinations were made in close succession on controls. None of the 3 compounds uniformly affected cardiac output in a single direction. The percentage change following injection varied from plus 185 to minus 45%. On the average, patients with high pre-injection outputs manifested a fall in output following administration of the test drug, while patients with low pre-injection outputs showed a rise. Many individual variations were observed, however. Output changes were due largely to altered stroke volume. Increased output was associated with a greater fall in intra-atrial pressure, a decreased arteriovenous oxygen difference and a rise in systemic blood pressure.

Xanthine studies 2) effects of aminophyllin, 1,3 diethyl 8 bromoxanthine and 1,3 dimethyl 8 chloroxanthine on water and sodium excretion. D. M. GREEN, W. C. BRIDGES, A. D. JOHNSON, J. H. LEHMANN, F. GRAY, and L. FIELD (all by invitation), *School of Medicine, Univ of Washington, Seattle, Wash.* The renal actions of 1,3-diethyl-8-bromoxanthine and 1,3-dimethyl-8-chloroxanthine were first observed by Newman and associates. In the present study these compounds have been compared with aminophyllin as to locus and intensity of effect. The subjects consisted of 25 hospital patients. Basal levels of renal function were measured during 2 20-minute clearance periods prior to intravenous injection of the drug. Drug effects were estimated by comparing control values with those obtained during 2 20-minute clearance periods following administration. All 3 compounds increased sodium and water excretion. Clearance data indicated these changes to be due almost entirely to a fall in percentage of tubular reabsorption. Aminophyllin was the most active of the compounds and doubled sodium output in 250 mg doses. The rise in water excretion was less than half as great. The glomerular filtration rate averaged an increase of approximately 15%. 1,3-diethyl-8-bromoxanthine was $\frac{1}{3}$ - $\frac{1}{4}$ as active as aminophyllin in augmenting sodium output. The effect on water excretion was proportionately less. Filtration rate changes were small and variable in direction. The renal effects of 1,3-dimethyl-8-chloroxanthine were inconstant and so weak as to

indicate the compound to be nearly inert. Analysis of aminophyllin action in relation to pre-injection levels of renal function showed the intensity of diuretic effect to be proportional to basal glomerular filtration rate. This relationship suggests that the effectiveness of the xanthines as diuretics depends on the renal functional reserve of the patient.

In vitro oxidation of oxophenarsine hydrochloride RAY E. GREEN (introduced by A. L. Tatum) *Dept. of Pharmacology, Univ. of Wisconsin Medical School, Madison, Wis.* The breakdown of oxophenarsine hydrochloride (mapharsen) on oxidation in air and 100% oxygen has been studied on various samples of the compound. The changes in LD-50 and minimal curative dose (M.C.D.) during the oxidation were determined for the albino rat and for *T. equiperdum* infection in the same species. An increase in the LD-50 and the M.C.D. has been noted on oxidation for both the aqueous solutions and the powdered compounds. When an aqueous solution is oxidized in pure oxygen for 24 hours or longer, a two- to three-fold increase in LD-50 (from 16 to 45 mg/kg) results and a dose $2\frac{1}{2}$ times the M.C.D. of the unoxidized compound is ineffective. The oxygen uptake in pure oxygen at 37°C has been followed manometrically and a linear relationship between oxygen consumption and time exists up to 25 hours of oxidation. Approximately 90% or more of the total decrease in toxicity occurs during this period. The effects of variations in pH on the rate of oxidation have been observed qualitatively over the range of pH 2.5 to 7. Increasing the pH value of the solution increases the rate of oxidation. At pH 2.5 and 25°C after 95 hours aeration, no demonstrable change in toxicity or therapeutic effectiveness was noted. On the other hand, at pH 7, for example, oxidation occurred very rapidly. In all instances examined, mapharsen upon oxidation became less toxic and correspondingly less effective as a trypanocide.

Effect of cholinesterase inhibitors on the permeability of dog erythrocytes in vitro MARGARET E. GREIG and WILLIAM C. HOLLAND (by invitation) *Dept. of Pharmacology, Vanderbilt Univ. Medical School, Nashville, Tenn.* In this laboratory it has been found that the intravenous administration of methadon to dogs frequently was followed by an increase in erythrocyte fragility and occasionally by a hemoglobinuria. Methadon also produced an increased hemolysis of dog and human erythrocytes *in vitro*. In metabolic experiments *in vitro* we have found that methadon inhibited the glycolysis of glucose, and the oxidation of lactate, pyruvate and succinate by brain (Arch. Biochem. 17, 129, 19, 441, 1948). Methadon also inhibited cholinesterase activity. Wilbrandt (Pflüger's Arch. f. d. ges. Physiol. 243, 519, 1940) reported that sodium fluoride and sodium iodoacetate produced changes in permeability of erythrocytes

which he attributed to their being glycolytic inhibitors. These compounds are, however, also inhibitors of cholinesterase activity. We have found that in addition to methadon certain more specific cholinesterase inhibitors which are reputed to have no effect on glycolysis, e.g., physostigmine, under certain conditions also produced changes in fragility of dog erythrocytes. The effect of these drugs was influenced markedly by the ionic composition of the medium.

New potent analgesic agent E. G. GROSS, M. A. BROTMAN (by invitation), S. F. NAGYFY (by invitation), W. W. SAWTELLE (by invitation) and L. L. ZAGER (by invitation) *Depts. of Pharmacology, Anesthesiology, Obstetrics and Gynecology, Urology and Surgery, State Univ. of Iowa, Iowa City, Iowa.* A new analgesic agent, 3-hydroxy-N-methyl morphinan hydrobromide (Nu-2206, Hoffmann-LaRoche, Inc.) is being studied experimentally and clinically in the above named departments. In the department of pharmacology, the analgesic potency of Nu-2206 has been studied using the Wolff-Hardy technique with normal human subjects, and the compound appears to have approximately four times the analgesic potency of morphine sulfate. With the highest dose used, 3 mg given subcutaneously, slight dizziness, nausea, vague gastro-intestinal symptoms and sedation were observed to a lesser degree than with a comparable analgesic dose of morphine sulfate. No euphoria was experienced by any of the subjects receiving the new agent. Blood pressure changes were slight and probably can be accounted for by the quieting of the subject. Respiration was only slightly depressed. Preliminary clinical reports indicate that the compound has about 3 times the potency of morphine sulfate when used in patients with incurable carcinoma and as a post-operative analgesic agent. The drug has also been used with moderate success in doses as high as 12 mg intravenously as the sole preanesthetic agent for nitrous oxide anesthesia, and there is some indication that the analgesia persists for a greater duration than is usual with other analgesic compounds.

Effect of diethylaminoethyl ester of 1-phenylcyclopentane-1-carboxylic acid hydrochloride, 'parpanit', on decerebrate rigidity, spinal reflexes and skeletal muscle CHARLES M. GRUBER, CHARLES P. KRAATZ (by invitation), CHARLES M. GRUBER, JR., and JOAN E. COPELAND (by invitation) *Dept. of Pharmacology, Jefferson Medical College, Philadelphia, Penna.* Seventeen decerebrated cats were used to study the effect of Diethylaminoethyl ester of phenylcyclopentane-carboxylic acid hydrochloride (parpanit) upon muscular rigidity. Four decapitated cats were used to determine the effect of parpanit upon reflexes, and 4 decerebrated cats and 11 urethanized dogs

to learn the effects of this drug upon motor nerve endings and on skeletal muscle, normal and denervated. Parpanit, trasentin and syntropan injected intravenously in adequate doses relieve the muscular rigidity of decerebrated cats. For this purpose these drugs were found superior to either atropine or scopolamine. The reflexes caused by mechanical stimulation of the back and paws in the spinal cat can be depressed by adequate doses of parpanit, trasentin and syntropan given intravenously. The height of the contractions of the anterior tibial muscle is increased with intravenous injections of parpanit. The intra-arterial injections of parpanit, trasentin and syntropan increase the height of the contractions of the anterior tibial muscle when their doses are small and rapidly injected and when their doses are large and slowly injected. Large doses rapidly injected cause a decrease in the activity of the muscle preceded and followed by increases above the height of the control. Parpanit, trasentin, syntropan, atropine and intocostin cause dilatation of the blood vessels in skeletal muscle when injected intra-arterially. The increased and decreased muscular activity following injections of parpanit and trasentin are direct effects of these drugs on the muscle cells, independent of the increase in blood flow. The depression of decerebrate rigidity by parpanit is due to central action and not a curare-like action on the neuromuscular junction.

Ganglionic blocking action of 'Dibutoline'

CARL C. GRUHZIT (by invitation) and GORDON K. MOE, *Dept of Pharmacology, Univ of Michigan, Ann Arbor, Mich.* Dibutoline, a quaternary ammonium compound with atropine-like properties, produces cardiovascular actions resembling those of tetraethylammonium. The ganglionic blocking action of Dibutoline was demonstrated in studies on arterial pressure, femoral arterial blood flow, and transmission through the stellate and superior cervical ganglia in dogs and cats. Intravenous injection of the drug causes a fall of pressure with an increased femoral blood flow, while intra-arterial injection causes little or no direct action on the vessels. Intravenous infusion blocks the respiratory and pressor actions of nicotine and high doses of acetylcholine and potentiates the pressor action of epinephrine. The effects of pre-ganglionic stimulation of the cardiac sympathetic nerves on heart rate and of the cervical sympathetic trunk on the nictitating membrane are blocked by Dibutoline, while the effects of post-ganglionic stimulation are uninhibited. The doses necessary to produce ganglionic blockade greatly exceed those said to produce atropine-like effects and would be encountered only with the highest doses used clinically.

Relative local emetic activity of glycosides of the digitalis series in cats. ROMULO GUEVARA (by

invitation), WALTER MODELL, THEODORE GREINER (by invitation), MELVIN MOORE (by invitation), ABRAHAM BLUMER (by invitation), HAROLD EVANS (by invitation) and HARRY GOLD, *Dept of Pharmacology, Cornell Univ Medical College, New York City.* All glycosides of the digitalis series exert local irritant action in the gastrointestinal tract. Whether this action is equally well developed in different glycosides has never been satisfactorily examined. Four glycosides, ouabain, scillaren A, scilliroside, and lanatoside C were compared. These were selected because they were available in pure form, their molecular weights and structures are known, and they are poorly absorbed from the gastrointestinal tract. Each of a series of doses of each compound was administered by stomach tube to a group of cats on an empty stomach (in all over 250 cats), and the animals were placed under continuous observation for a period until the first sign of vomiting or for at least 12 hours. The percentage of animals in which there was an emetic response for each of the series of doses was plotted against the log of the dose. The results show that the property of local emetic activity is developed to widely different degrees in the molecular structure of the various digitalis glycosides, and the ones tested here show the following order of increasing approximate potencies: ouabain-1, scillaren A-4, lanatoside C-10, scilliroside-10. That the emetic action was local was assumed from the fact that intravenous assay following emesis disclosed a systemic action of only from about 10 to 20% of the fatal dose. Local emetic action delayed in some cases for as long as 10 hours was an unexpected observation. There was no relation between the cardiac potency and the local emetic action.

Study of coca addiction. CARLOS GUTIERREZ-NORIEGA, *Dept of Pharmacology, Universidad Nacional Mayor de San Marcos, Lima, Peru.* The use of coca leaves is limited chiefly to the Andes regions of South America, from Colombia to Argentina. In regions where coconism exists, 25 to 30% of the total population are coca chewers. The number of coca chewers of South America may be estimated to be 8 millions. The amount of coca leaves annually consumed is, at least, 14,000 tons. The individual daily dose varies between 10 and 100 grams, with 30 grams as a mean value. The extraction of alkaloids during a period of coca chewing varies from 66% to 96%, with 86% as a mean value, in respect to the total amount of alkaloids contained in coca leaves. The total amount of alkaloids consumed varies from 80 to 400 mg, with 180 mg as a mean value. There is no increase in tolerance to cocaine among the coca chewers. The differences between the amounts of alkaloids ingested by the addicts of short-standing and of long-standing use are very small. The daily dose

of coca leaves does not increase during the span of life of the addicts. The duration of the coca chewing habit is more responsible than the size of the daily dose as a cause of the chronic symptoms found among coca chewers.

Toxicity to rats of diallyl acetic acid and other compounds containing the allyl radical ERNEST C HAGAN (by invitation), GEOFFREY WOODARD (by invitation), and ARTHUR A NELSON *Div of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D C* Rectal suppositories containing the bismuth salt of diallyl acetic acid have been held responsible for a number of deaths in children. Implications are that the acid is the responsible chemical. The oral LD50 of diallyl acetic acid (DAA) for rats is in the neighborhood of 630 mg/kg, diallyl phthalate 770, diallyl adipate 750, and allyl alcohol 60. Intravenously DAA has the same LD50 as by oral administration. Symptoms of poisoning by these compounds are depression, arching of the back, ruffled coat, and generalized weakness with anorexia. Deaths, particularly with DAA, are delayed, some occurring several weeks after acute dosage. At autopsy gross examination of the organs shows the livers and kidneys to be pale. In addition the livers present a nutmeg appearance. Microscopically both organs show principally fatty degeneration which is generally more severe in the liver than the kidney. Data obtained from feeding DAA at 25, 50, and 100 ppm for 6 months to Osborne Mendel rats demonstrate growth suppression in female rats at all levels, and in male rats at 50 and 100 ppm. Females show as much inhibition at 25 as at 50 ppm, while males at 25 ppm show growth comparable to that of their control animals. The capacity for detoxification of pentobarbital and phenobarbital was studied in rats which had received 100 ppm DAA for from 1-2 months. With each barbiturate hypnosis was more prolonged in treated animals than in their litter controls.

Correlation between toxicity by inhalation and physical properties of beryllium oxide R H HALL, S LASKIN, G SPRAGUE and B H BROWN (introduced by H C Hodge) *Dept of Radiation Biology, Univ of Rochester, Rochester, N Y* The toxicity of inhaled BeO appears to depend upon the physical properties of the material, which, in turn, are related to the method of preparation. The processes currently employed in the production of BeO involve calcining a beryllium salt at high temperatures. Dogs, guinea pigs, rabbits and rats have been exposed 6 hours daily for 12-15 days to an atmosphere containing approximately 85 mg/m³ of BeO aerosol. Even at this relatively high concentration, one grade of BeO appeared to be virtually nontoxic. This material was fired at 1350°C and was composed of unit particles having an arithmetic mean diameter of about 0.7μ, with

aggregates of low porosity (5.2%). A second grade of BeO gave definite evidence of toxicity. This material was fired at 1100°C and comprised unit particles of about 0.5μ diameter, with aggregates of markedly greater porosity (35%). Two of 20 rats died during the exposure period, while 3 of 5 rats, held for observation following exposure, showed a marked increase in their leukocyte count due to an absolute increase of neutrophils and lymphocytes. One of 4 dogs showed a transient low blood oxygen tension following exposure, and the lungs of this animal which was killed terminally exhibited extensive lesions. Dogs and rats exposed to an aerosol of BeO produced by calcining Be(NO₃)₂ at 400°C exhibited weight loss during exposure, 1 of the 2 dogs showed a significant reduction in blood oxygen tension, and 8 of 40 rats died. This material was made up of unit particles of about 0.4 microns mean diameter and aggregates of very high porosity (134%). The small sizes were confirmed by x-ray diffraction analysis which also revealed trace quantities of a foreign substance identified as silica. On heating of the material at 1000°C, grain growth occurred followed by the disappearance of the silica lines.

Effect of mercurial diuretics on the succinic dehydrogenase system of the kidney C A HANDLEY *Dept of Pharmacology, Baylor Univ College of Medicine, Houston, Texas* The succinic dehydrogenase activity of rat kidney cortex homogenate was inhibited 20-50% by the intravenous administration of non-lethal doses of mercurial diuretics. The dosage range used was 0.1 to 0.2 cc/kg (4-8 mg/kg of combined mercury), the range generally used for diuresis in laboratory animals. One hour after the injection, the kidneys, liver and heart were removed and 5% homogenates of each organ prepared for assay. In none of the experiments was the succinic dehydrogenase activity of heart or liver reduced below that of the controls. When the mercurial diuretic was added directly to Warburg flasks containing homogenates of kidney cortex, liver and heart from untreated animals, so that the concentration of mercury was 5×10^{-6} to 10^{-6} M, a comparable inhibition of succinic dehydrogenase activity occurred in all the homogenates. It is concluded that during mercurial diuresis, sufficient mercury is accumulated in the kidney cortex to partially inhibit the succinic dehydrogenase activity.

Amebicidal action of agents inhibitory to associated bacteria in vitro EDER L HANSEN (introduced by Hamilton H Anderson) *Div of Pharmacology and Experimental Therapeutics, Univ of California Medical School, San Francisco, Calif* *E. histolytica* has not yet been cultivated in the absence of bacteria. Agents that affect trophozoites may do so either directly or indirectly by acting on associated bacteria (Brickett & Bliz

nick, 1947) It is now possible to detect indirect (bacteriostatic) action by modification of the conventional testing procedure, so that the intense reduction produced by associated bacteria is preserved Such reducing conditions are necessary for survival and multiplication of trophozoites, since slight disturbance of bacterial growth can result in death of the ameba Tubes containing dilutions of any agent found to be 'amebacid' when tested by conventional procedure were sealed with melted petrolatum (Shaffer & Frye, 1948) Survival of trophozoites in sealed cultures, after 48 hours at 37°C, indicated that apparent 'amebacid' action observed in cotton-stoppered tubes was due to inhibition of bacteria and not necessarily to direct action on the ameba The method has been applied to Locke's egg slants and to the two liquid media of Hansen & Anderson (1948), using as bacterial associates organism 't' or a 2-membered flora With the latter flora selective action of an inhibitory agent further complicated evaluation of amebacid activity Aureomycin HCl was 'apparently amebacid' in liver-proteose-peptone medium at 1/500,000, however in sealed cultures, trophozoites survived in concentrations of 1/50,000 At higher concentrations organism 't' was so greatly inhibited that satisfactory reducing conditions were not established even in sealed cultures Emetine HCl which exhibited no bacteriostatic action, was amebacid at the same concentrations in both cotton-stoppered and petrolatum-sealed cultures

Comparison of effects of injection of pyrogenic solutions by intravenous and intramuscular routes WILLIAM D HARKNESS (by invitation) and BERT J Vos *Div of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D C* Rabbits were injected either intravenously or intramuscularly with a pyrogenic solution prepared from *Pseudomonas aeruginosa*, and their rectal temperatures were observed at hourly intervals for 5 and 5 hours respectively The rise in temperature following intramuscular injection was more gradual than that following intravenous injection and frequently had not reached a maximum even at 5 hours Within certain limits a linear relationship existed between log dose of pyrogen and the maximum rise in temperature observed during the experimental period However, at least 4 times as much pyrogen was needed by intramuscular as by intravenous administration to produce a given rise in temperature

Pathologic changes in guinea pigs produced by diets deficient in the anti-stiffness factor PAUL N HARRIS and ROSALIND M WULSEN (by invitation) *The Lilly Research Labs, Eli Lilly and Co, Indianapolis, Ind, and the Dept of Zoology, Oregon State College, Corvallis, Ore* It was found by Wulsen and Bahrs (*Am J Physiol*

133 500, 1941) that maintenance of guinea pigs upon pasteurized milk or skim milk diets resulted in stiffness of the wrists Diets of skim milk powder dissolved in skim milk or water and supplemented with ferric chloride, copper sulfate and adequate amounts of the known vitamins have a similar effect, and were used in the studies herein reported Hamsters kept upon such diets remained normal, but guinea pigs developed widespread anatomical lesions These consisted in necrosis of skeletal muscle with a variable amount of macrophage infiltration and foreign body giant cell formation and calcification of necrotic fibers, focal necrosis and calcification of the myocardium, deposition of calcium salts in the smooth muscle of the gastrointestinal tract, and in the kidneys, liver, aorta and peripheral arteries, and development in the muscles and adjacent to bones and joints of abscesses that often became calcified

Skin penetration of radioactive anticholinesterases—a direct quantitative method of study E ROSS HART, JOSEPH H FLEISHER (by invitation), and AMEDEO S MARRAZZI *Toxicology Section, Medical Div, Army Chemical Center, Md* Any study of the ability of a compound to penetrate the skin necessitates some means of determining its concentration in the blood Chemical methods that are sufficiently specific and sensitive are often lacking Moreover, they require repeated sampling thus disturbing the animal economy and providing only discontinuous determinations Pharmacological methods are of limited usefulness because of their inherent lack of precision and their indirectness, latent periods, compensatory mechanisms etc, all introducing complications Radioactive tracer methods offer the advantages of being highly sensitive and specific and, as utilized here, requiring no sampling, being essentially direct and continuous Increased sensitivity and specificity can be attained by measuring the radioactivity of venous blood draining from the area of application thus avoiding dilution in the entire blood volume and minimizing the possibilities of chemical alteration between penetration and determination The rabbit ear seems almost ideally suited to our purpose By applying tagged compounds to the distal portions and placing a Geiger-Mueller tube over the proximal portions of the marginal vein, we have accomplished the conditions outlined above Information concerning routes of penetration can be obtained from radioautographs of cross sections of the ear The technique is described in detail and the results of its application to DFP are presented as an example

Streptomycin content of brain and other tissues after parenteral injection J E HAWKINS, JR, G E BOXER, and V C JELINEK (by invitation) *Merck Inst for Therapeutic Research and The Research Labs of Merck & Co, Rahway, N J*

The streptomycin content of blood, cerebrospinal fluid, brain, liver, lung and spleen was determined by the fluorometric method in 3 cats killed 24, 48 and 72 hours respectively after receiving a subcutaneous injection of streptomycin CaCl_2 -complex equivalent to 400 mg of streptomycin base/kg of body weight. The blood concentration at 24 hours was too high for the tissue concentrations to be meaningful. At 48 and 72 hours, when the blood and cerebrospinal fluid concentration had fallen to 1-2 $\mu\text{g/ml}$, the viscera contained 9 to 38 $\mu\text{g/gm}$ (wet weight) but the brain only 2-4 $\mu\text{g/gm}$. This experiment shows that streptomycin tends to persist in the viscera when it has virtually disappeared from the body fluids, but has no special predilection for the brain. In a second experiment similar determinations were made in 4 cats which had received daily doses of streptomycin equivalent to 100 mg of base/kg for 7 to 28 days. All but one showed the characteristic vestibular disturbance. Blood and cerebrospinal fluid taken 24 hours after the last dose of streptomycin contained 1-3 $\mu\text{g/ml}$ and the brain only 1-2 $\mu\text{g/gm}$, while the concentration in lungs, liver, spleen and salivary glands ranged from 7 to 41 $\mu\text{g/gm}$, and in the kidneys from 119 to 234 $\mu\text{g/gm}$. The significance of these observations is discussed in relation to the therapeutic and neurotoxic actions of streptomycin. It is evident that the neurotoxic action does not depend upon a selective accumulation of the drug in the brain.

Pharmacology and toxicology of thiodipropionic acid and its dilauryl and distearyl esters LLOYD W. HAZLETON and REBECCA C. HELLERMAN (by invitation) *Hazleton Labys, Falls Church, Va.* Thiodipropionic acid ($\text{S}[\text{CH}_2\text{CH}_2\text{COOH}]_2$) and its dilauryl and distearyl esters have antioxidant properties of interest in the preservation of edible fats and oils. The acid is slightly soluble in water while the esters are insoluble over a wide range of temperatures. In rats, mice and guinea pigs the acute toxicity of these compounds is of a relatively low order of magnitude. Infused intravenously in anesthetized dogs the lethal dose of the acid is in excess of 10 gm/kg. The acid possesses no characteristic pharmacological properties and death in these animals is apparently due to hemodilution and acidosis. Two-year rat feeding experiments were essentially negative for the acid and distearyl ester in levels up to 3.0% of the diet. The 3.0% dilauryl level showed an increase in mortality toward the end of the period. In another series a mixture of the acid and dilauryl ester was heated in lard at 190°C for 30 minutes. The diets as fed contained 10% lard plus 0.11% and 1.1% of the acid-ester mixture. At the lower level there was no significant effect on growth or mortality during the 2-year period. At the higher level there was significant mortality during the first year. The

immediate cause of this increased mortality was respiratory infection. The possible role of the diet in this phenomenon was not established. Based on a 2-year expectancy, all the groups showed from 83% to 99% of the theoretically perfect score with the exception of the two groups discussed which showed 75% and 37% respectively.

A new adrenergic blocking agent FRANCIS G. HENDERSON (by invitation) and K. K. CHEN *The Lilly Research Labs, Eli Lilly and Co., Indianapolis, Ind.* A study was made with ethyl β -chloroethyl β -*o*-benzyl) phenoxyethylamine HCl. Its adrenergic blocking activity was found to be approximately 7.5 times that of dibenamine, but its toxicity greater than that of the latter, the LD_{50} in mice by intravenous injection being 33.81 ± 1.28 mg/kg as against 88.45 ± 3.02 mg/kg for dibenamine. A dose of 2 mg/kg intravenously reversed the pressor response ordinarily produced by 25 μg of epinephrine HCl in the dog under barbiturate anesthesia. When a dose of 5 mg/kg was given intravenously the reversal action persisted for over 30 hours. A reversal of the pressor action of epinephrine also occurred 25 hours following the oral administration of this compound in the dose of 20 mg/kg mixed in an acacia suspension. A dose of 5 mg/kg intravenously prevented the rise in blood pressure commonly produced by intravenous injections of 1 mg of the following aliphatic amines: 2-aminoheptane sulfate, 2-amino-4-methylhexane sulfate, and 2-methylamino-1-cyclopentylpropane HCl. No epinephrine reversal could be demonstrated on the cat's uterus. When administered to dogs by slow intravenous injection in doses ranging from 2 to 10 mg/kg, the compound per se caused no significant changes in blood pressure, respiration or electrocardiogram.

Effect of myanesin on extrapyramidal facilitatory and inhibitory systems E. HENNEMAN (by invitation), A. KAPLAN (by invitation) and K. UANA *Depts. of Psychiatry and Pharmacology, Univ. of Illinois College of Medicine, Chicago, Ill.* Hyperactivity of stretch reflexes due to overactive or unopposed extrapyramidal facilitation constitutes spasticity. Demonstration of the origins of separate spinal paths for facilitation and inhibition of myotatic reflexes in two distinct regions of the brain stem (Magoun) suggested investigation of the effects of myanesin on these systems. Bipolar stimulating electrodes carried in a stereotaxic apparatus were used to explore the bulbar reticular formation in lightly nembutalized cats. Regions yielding complete inhibition (medial, medullary sites) or satisfactory facilitation (lateral, pontine sites) of the knee jerk with low voltage were located. Myanesin was administered intravenously. Small doses reduced facilitation or inhibition. Larger doses abolished either effect but left the knee jerk, as judged by amplitude, unaffected.

The two antagonistic systems were influenced equally so far as could be judged. The time course of drug action was determined by following the recovery of such systems. Inhibition and facilitation of the knee jerk resulting from cerebral cortical stimulation were abolished with much smaller doses, suggesting that longer or more complex circuits (such as are usually involved in spasticity) are more vulnerable to myanesin. Purely spinal facilitatory or inhibitory reflex arcs were also investigated by stimulating peripheral skin or muscle nerves in decapitate preparations. From this type of evidence and from electrical studies of segmental spinal reflexes it appears that myanesin relieves spasticity by reducing tonic extrapyramidal facilitation of stretch reflexes, whatever its source. Because facilitation dominates inhibition in spasticity it is presumably more affected by the drug.

Cardiovascular action of magnesium sulfate solutions JAMES P. HENSEN (introduced by R. P. Ahlquist) *Dept. of Pharmacology, Univ. of Georgia School of Medicine, Augusta, Ga.* The cardiovascular actions of magnesium sulfate solutions, administered intravenously and intra-arterially, were investigated in the anesthetized dog. Arterial pressure was recorded by means of either an optical manometer or an ordinary mercury manometer while the femoral arterial or venous blood flow was recorded by a rotameter or 'Bubblemeter'. The results indicate that magnesium sulfate solutions lower the arterial pressure by two different mechanisms: 1) peripheral vasodilation and 2) myocardial depression. The peripheral dilation was found to be due to 1) a direct action of the magnesium ion (an effect proportional to the dose administered) and 2) some osmotic action (an effect proportional to the concentration of the injected solution). This osmotic effect was most pronounced with intra-arterial injections and could be duplicated by intra-arterial injections of hypertonic sodium chloride solutions. No evidence was obtained to indicate that the vasodilating action of magnesium sulfate was due to ganglionic blockade in a manner analogous to tetraethylammonium.

Pharmacologic properties of 2-[N-p'-tolyl-N-(m'-hydroxyphenyl) - aminomethyl] - imidazole hydrochloride (C-7337), a sympatholytic ELIZABETH A. HEROLD (by invitation), ANNE CAMERON (by invitation), ALFRED EARL (by invitation), FRANK ROTH (by invitation), JAMES SMITH (by invitation), NICOLINE SMITH (by invitation), ELIZABETH SORESENSEN (by invitation), BRADFORD N. CRAVER *Div. of Microbiology, Research Dept., Ciba Pharmaceutical Products, Inc., Summit, N. J.* This drug was synthesized by Marxer and Miescher and reported by Meier and Yonkman (*Federation Proc.*, this issue). Doses of 0.2 to 1.0 mg/kg have produced 'epinephrine reversal' in dogs, cats, guinea pigs and rats. C-7337,

in sufficient dosage, produced the hypotension characteristic of sympatholytics. Other augmentatory actions of epinephrine negated by C-7337 in the same range of doses were 1) contraction of nictitating membrane and 2) salivation in the cat. About twice the doses required for adrenolysis sufficed for sympatholysis. The spasmolytic effect of epinephrine upon canine Thiry-Vella loops and upon the feline uterus was unaltered by the drug. It produced complete relaxation of the nictitating membrane in respect to such drugs as Priscol and Privine, whereas atropine produced only partial relaxation; this could be but partly explained by its very weak antihistaminic and anticholinergic activities. In Warburg experiments cardiac tissue from the cat was as sensitive to the inhibitory action of C-7337 on respiration as hepatic tissue from the cat or rat (100 γ /ml — minimal inhibitory concentration). The LD₅₀ in rats is 55 mg/kg intravenously. In the dog 125 mg/kg orally produced depression, tachycardia, defecation, salivation, emesis and recovery; 60 mg/kg intravenously produced the same symptoms and final recovery. Warren, Woodbury and Trapold (*this issue Federation Proc.*) will report an intensive study of the effects of its chronic administration to dogs.

A rapid method for the determination of inulin in blood and urine AEME HIGASHI (by invitation) and LAWRENCE PETERS *Dept. of Pharmacology, School of Medicine, Western Reserve Univ., Cleveland, Ohio*. Bacon and Bell (*Biochem. J.* 42: 397, 1948) used a modified Selwanoff reaction, devised by S. W. Cole, to determine fructose in cadmium sulfate filtrates of blood. They mentioned its application to the determination of inulin. We failed to recover added inulin consistently from blood and urine by this method. However, when a trichloroacetic acid (TCA) rather than a CdSO₄ filtrate was used, and temperature was controlled within 0.5°C, accurate recoveries resulted. To 2.0 ml of plasma or urine filtrate (80% TCA), containing 7.5–30.0 γ of inulin, is added 3.0 ml of 0.15% resorcinol in alcohol (95%). With the tubes immersed in ice water, 3.0 ml of conc. HCl, containing 7.5 mg of FeCl₃/l, are added with shaking. The tubes are heated in a water bath for 20 minutes at 79.0–79.5°C. After rapid cooling, the orange-red color is read in a Klett colorimeter (54 filter). Standard solutions are analyzed with unknowns on all occasions. Plasma containing no inulin gives blank readings equivalent to 0.7–1.4 mg %. Urine from subjects undergoing clearance studies is diluted beyond the point where blank values are obtained. Glucose produces additional color requiring corrective calculation only at high concentrations, such as those obtained during Tm determinations. Numerous recovery experiments have yielded a maximum error of 2.5%. Simultaneous inulin and creatinine clearance values for dogs agree well.

In one experiment the average I/C ratio for 9 consecutive clearance periods was 1.036 (range, 0.99–1.08, S.D. 0.032)

Lack of antagonism of methionine to barbiturates J. EUGENE HILL (by invitation), P. L. EWING, G. A. EMERSON and MELVILLE SAHYUN, *Dept. of Pharmacology, Univ. of Texas Medical Branch, Galveston, Texas, and The Sahyun Lab., Santa Barbara, Calif.* The nutritional significance of methionine suggests a possible antagonism by it of agents detoxified in the liver. White mice treated with tolerated doses of 0.1–0.5 gm/kg of DL-methionine intramuscularly or intraperitoneally were given repeated intraperitoneal doses of hexobarbital or thiopental at short intervals until approximately 50% of untreated controls died, or single intraperitoneal doses of the LD₅₀ of pentobarbital or phenobarbital. In each case, a larger proportion of the methionine-treated mice died than of the controls. With pentobarbital, mice fasted 24 hours again showed no protective effect of methionine. Methionine either is present in excess even in fasted mice or else is not involved in the major degradation reactions of barbiturates in the liver.

A polarographic study of certain quinones JAMES G. HILTON (introduced by C. L. GEMMILL), *Dept. of Pharmacology, Univ. of Virginia Medical School, Charlottesville, Va.* The polarograph has been used as a qualitative and quantitative instrument in the study of certain quinones. The quinones examined were hydroquinone, 2-methylhydroquinone, 2,3-dimethylhydroquinone, 2,3,5-trimethylhydroquinone, 1,4-naphthoquinone, 2-methyl-1,4-naphthoquinone, 2-methyl-3-hydroxy-1,4-naphthoquinone (Phthiocol), 3-hydroxy-1,4-naphthoquinone (Lawsone) and sodium 1,2-naphthoquinone-4-sulfonate. These quinones were studied both in bicarbonate and in glycolytic enzymatic mediums. All of the quinones showed definite half-wave potentials in the bicarbonate-carbon dioxide solution and gave diffusion currents which were in direct proportion to the concentrations. A detailed study was made of the half potentials of 2-methyl-3-hydroxy-1,4-naphthoquinone (Phthiocol) at various levels of oxidation of this compound. A close correlation was obtained between these potentials and the oxidation-reduction potentials previously described by Ball (*J. Biol. Chem.* 106:515, 1943). In the glycolytic enzymatic systems, the half potentials were shifted and the diffusion current heights were either reduced or totally missing. It is concluded from this work that the polarograph is an accurate instrument for determining the concentration of certain quinones of as low as 1×10^{-4} M concentration in a bicarbonate medium and is suitable also for determining oxidation-reduction potentials of these compounds in bicarbonate

buffered solutions. From these results in the glycolytic enzymatic systems, it is concluded that the half potential shift was due to a change in the oxidative level of the quinone system and the diffusion current variations were due either to combination or to destruction of part or all of the quinone.

Acute toxicity of hydroquinone HAROLD C. HODGE, ELLIOTT A. MAYNARD (by invitation) and JAMES H. STERNER (by invitation), *Div. of Pharmacology and Toxicology, Dept. of Radiation Biology, Univ. of Rochester School of Medicine and Dentistry, and Eastman Kodak Company, Rochester, N. Y.* The characteristics of acute hydroquinone poisoning have been observed. Dying animals did so promptly, those surviving 20 minutes almost invariably recovered completely. Convulsions were commonly observed, the heart frequently beat after respiration ceased. Estimations of the LD₅₀ have been made for a number of species. Following intraperitoneal administration, mice, rats, guinea pigs and rabbits have similar LD₅₀'s. After oral administration, cats were most susceptible, rats and rabbits less so, and mice most resistant. Cats can, however, ingest approximately the lethal dose daily for nearly a month if the HQ is mixed in the diet. Fasting rats were twice as susceptible as fed rats to oral doses. The LD₅₀ (orally to rats) of HQ in propylene glycol was considerably greater than in water solution. Rats were maintained for a period of one month on a) a common laboratory mixed diet and b) a commercial rat ration, the acute LD₅₀'s (oral administration) were identical regardless of previous diets. The acute toxicity of commercial photographic-grade hydroquinone was the same as that of a carefully purified sample when each was administered intraperitoneally.

Relationship of chemical structure to biliary concentration in experimental cholecystography JAMES O. HOPPE and S. ARCHER (introduced by A. M. Lands), *Biology Div., Sterling-Winthrop Research Inst., Rosenslaer, N. Y.* Replacement of one of the hydrogens from the methyl group of 4-amino-3,5-diiodotoluene by 2-substituted n-alkanoic, cycloalkyl-alkanoic or aryl-alkanoic acids yielded compounds which were excreted into the bile of cats following oral administration in sufficient amounts to make the gallbladder opaque to x-radiation. Optimum results were obtained with the n-alkanoic acid derivatives when the number of carbon atoms attached to the phenyl nucleus approached seven. The cycloalkyl-alkanoic acid derivatives were ineffective because of poor absorption. The most satisfactory compound was found among the aryl-alkanoic acid derivatives in the form of the sodium salt of β -(4-amino-3,5-diiodophenyl)- α -phenyl propionic acid (WIN 593-2). The density of the shadows produced by WIN

508-2 appeared to be approximately 15 times as great as those of iodoaliphonic acid at comparable dose levels. Upon oral administration to both cats and dogs, WIN 508-2 appeared to be relatively non-irritating to the gastro-intestinal mucosa, readily evacuated from the gallbladder following a fatty meal and to produce a minimum of vomiting and diarrhea. The acute oral toxicity of the free acid in mice was less than that of iodoaliphonic acid whereas that of the sodium salt, WIN 508-2, was slightly greater because of more rapid and efficient absorption.

Metabolic studies in beryllium patients JOE W. HOWLAND and CHRISTINE WATERHOUSE (introduced by H. C. Hodge) *Dept of Radiation Biology, Univ of Rochester, Rochester, N. Y.* Systemic manifestations of weakness, easy fatigability, anorexia, and weight loss have played an important role in the symptomatology of many patients with beryllium granulomatosis. Metabolic studies were carried out on 4 patients with beryllium poisoning in an attempt to determine whether or not these patients were able to utilize and store nitrogen on an adequate dietary intake. Three of the 4 patients studied were malnourished, had lost between 30 to 40 pounds in weight during their illnesses. Yet none was able to establish a significant positive nitrogen balance on diets adequate in calories and protein. Fecal nitrogen was high on all 3 patients. Under the anabolic stimulus of testosterone, one patient had a negligible nitrogen storage response, however, another stored moderate amounts of nitrogen under this regime. The implications of these findings particularly in reference to anoxia and to the systemic effects of beryllium poisoning are discussed.

Effect of quinidine in cyclopropane and cyclopropane-epinephrine induced arrhythmias R. A. HUGGINS (by invitation), R. A. MORSE (by invitation), D. W. CHAPMAN (by invitation), C. A. HANDLEY, and L. F. SCHUHMACHER (by invitation) *Depts of Pharmacology, Medicine and Anesthesiology, Baylor Univ College of Medicine, Houston, Texas*. The protective action of intravenous quinidine sulfate and lactate against the onset of epinephrine induced cardiac arrhythmias under cyclopropane anesthesia has been evaluated as to rapidity of onset, duration of action and minimum effective dose. The dosages used were 1, 5, 10, and 20 mg/kg. The intravenous administration of quinidine sulfate or lactate in all dosage levels tested markedly reduced the incidence of this type of cardiac arrhythmia. No difference was found between the two forms of quinidine. The onset of the protective action was rapid, less than 0.5 minute after the completion of the injection, and independent of the dosage. Injections of epinephrine up to 10 minutes after the administration of quinidine caused no arrhythmias, regardless of the size

of the dose. After 10 minutes, the duration of the protecting properties of quinidine tends to vary directly with the size of the dose, lasting for an average of 24 minutes with 1 and 5 mg/kg, and 1 to 3 hours with 20 mg/kg.

Failure to demonstrate biological competition between hypnotic and non-hypnotic barbiturates WALTER W. JETTER, ROBERT P. BRITAIN and MARY K. NUTER (introduced by George L. Maison) *Dept of Legal Medicine, Harvard Medical School, and The Massachusetts Dept of Mental Health, Boston, Mass.* Sodium salts of non-hypnotic barbituric acid derivatives (BAD) as follows: 1) 5-monoethyl, B. A., 2) 5-monophenyl, B. A., 3) 5-mono sec butyl, B. A., 4) 5,5-ethyl, nitropropyl, B. A., 5) 5,5-methyl (1 methyl butyl), B. A., 6) 5,5-methyl (1 methyl butyl) 4-imino, B. A. furnished in small quantities by Abbott Laboratories, North Chicago, were tested for their analeptic properties against depressant barbiturates in the following way. Twenty-seven rabbits were anesthetized by intravenous pentobarbital (40 or 50 mg/kg) and 26 by phenobarbital (150 or 175 mg/kg). Four rabbits died within less than one hour after receiving the depressant barbiturate alone. The surviving group of 49 rabbits contained 24 animals that received pentobarbital and 25 that received phenobarbital. Fifteen of these (9 pentobarbital and 6 phenobarbital) served as controls and received no treatment. Each of the remaining 34 animals then received intravenously one of the six BAD test compounds in dosage of 50, 100, or 150 mg/kg. Each compound was tested in at least 4 rabbits (BAD no. 5 was not tested against phenobarbital because of insufficient supply). It was clear that in no instance did the injection of the test BAD compound significantly decrease the depth or duration of the anesthesia caused by the previously injected depressant barbiturate. It was concluded that the BAD compounds tested were not successful biological competitors against pentobarbital or phenobarbital under the conditions of the experiment.

Effect of antimalarial drugs on anaerobic glycolysis (acid production) in tissue extracts RALPH JONES, JR (introduced by Carl F. Schmidt) *Dept of Research Medicine, Univ of Pennsylvania, Philadelphia, Penna.* A study was made of the effect of several antimalarial drugs on anaerobic production of acid from glucose by rat brain extract, in the system described by Utter, Wood and Reiner (*J Biol Chem* 161:197, 1945). Pentaquine and Pamaquin produced significant inhibition of acid production when present in concentration of 5×10^{-4} M. Quinine, Quinacrine, Chloroquine and Paludrine produced no significant inhibition when present in concentration of 2×10^{-3} M. The system described by Utter *et al* was modified in an attempt to localize the site of inhibition of acid

508-2 appeared to be approximately 15 times as great as those of iodoaliphonic acid at comparable dose levels. Upon oral administration to both cats and dogs, WIN 508-2 appeared to be relatively non-irritating to the gastro-intestinal mucosa, readily evacuated from the gallbladder following a fatty meal and to produce a minimum of vomiting and diarrhea. Effect of antimalarial drugs on anaerobic glycolysis (acid production) in tissue extracts RALPH JONES, JR (introduced by Carl F. Schmidt) *Dept of Research Medicine, Univ of Pennsylvania, Philadelphia, Penna*. A study was made of the effect of several antimalarial drugs on anaerobic production of acid from glucose by rat brain extract, in the system described by Utter, Wood and Reiner (*J Biol Chem* 161:197, 1945). Pentaquine and Pamaquin produced significant inhibition of acid production when present in concentration of 5×10^{-6} M. Quinine, Quinacrine, Chloroquine and Paludrine produced no significant inhibition when present in concentration of 2×10^{-3} M. The system described by Utter *et al* was modified in an attempt to localize the site of inhibition of acid

production. Inhibition of the same order of magnitude occurred when Hexose diphosphate was the substrate, when Fluoride is present in concentration of 0.02 M, and when arsenate is substituted for phosphate in the system. These results indicate that these compounds interfere with the conversion of Hexose diphosphate to Phosphoglyceric acid. Studies of the mechanism of this inhibition are in progress. The effect of twenty 8-aminoquinoline analogues of Pamaquine and Pentaquine on acid production in these systems was studied. Alteration of chemical structure modified the ability of these compounds to inhibit acid production, but there was little correlation between inhibition of acid production and antimalarial activity.

Effects of ions and enzyme inhibitors on breakdown of pentobarbital by rat liver slices. I. B. KAHN, JR. (introduced by J. M. Coon) *Dept of Pharmacology, Univ of Chicago, Chicago, Ill.* Although it is well established that some barbiturates are detoxified by tissues *in vitro*, the nature of the process is not well understood. It was therefore decided to study the effects of various ions upon the action of rat liver slices on pentobarbital. The ions studied are known to be effective in activating or inhibiting enzymatic reactions of various types. Approximately 200 mg of liver slices were placed in each of two 250-ml Erlenmeyer flasks, A and B, each containing 90 ml of Krebs Ringer bicarbonate buffer with glucose. A was boiled for 5 minutes while B was maintained at 37°. Both were placed, in a water bath at 37°, and 10 ml pentobarbital, 0.6 mg/ml in Krebs-Ringer bicarbonate buffer added. Air was bubbled through for mixing and oxygenation. Ten-ml aliquots were taken from each at 0, 30, 60, and 120 minutes, and analyzed for unchanged barbiturate by a modification of the method of Goldbaum (*J Pharmacol* 94: 68, 1948). Controls in normal Krebs-Ringer bicarbonate buffer with glucose showed 10% destruction of pentobarbital in 60 and 120 minutes in flask B, while flask A remained constant. Doubling the concentration of potassium and omitting calcium had no effect. The effects of high and low concentrations of Na, K, Ca, and Mg, and of heavy metals, iodoacetate, and cyanide are also reported.

Effect of acetate donors on creatinine levels in blood and urine in dogs. A. KANDEL (by invitation) and MAYNARD B. CHENOWETH *Dept of Pharmacology, Univ of Michigan, Ann Arbor, Mich.* Five unanesthetized dogs were injected intramuscularly, and one intravenously, with monoacetin (glycerol monoacetate). Bladder urine was collected by catheter for a period of 10 hours. As a control, urine was collected over periods of the same length but without administration of monoacetin. The intramuscular injection of monoacetin resulted in a 25% increase in the total

amount of creatinine excreted. An 80% increase was observed in the animal in which a 5% solution of monoacetin was given intravenously. Creatinine was not excreted during control periods, but appeared in the urine only after monoacetin was administered. Both creatine and creatinine are excreted in greatest amounts during the last 2 hours of the collection period. Intramuscular injection of propylene glycol in one of the animals revealed no increase in urinary creatinine. A bilaterally nephrectomized dog was given 1 gm/kg monoacetin intramuscularly in 1 gm/kg doses every 2 hours. Blood collected at hourly intervals showed a steady increase in the creatinine level. A marked augmentation in creatinine accumulation was observed during the 9th and 10th hours. Further experiments are being conducted to establish the nature of the increase in production of creatine congeners by acetate donors.

Chronic effects of large doses of acetanilid in dogs and rats. ALEXANDER G. KARCZMAR (introduced by Theodore Koppányi) *Dept of Pharmacology, Georgetown Univ School of Medicine, Washington, D. C.* This is an extension of a study of acute toxicity of acetanilid (700 mg/kg) in dogs (*Federation Proc* 6: 311, 1947). Daily oral administration of 100 mg/kg of acetanilid caused no withdrawal symptoms after 3 weeks (2 dogs). Administration of 150, 100, and 200 mg/kg (2, 2, and 7 weeks, Payne, *J Pharmacol Exper Therap* 53: 401, 1935) was followed by daily methemoglobin cycles (duration 8 hr) with peaks of 25, 15 and 35% of total hemoglobin respectively. Discontinuation of acetanilid in 1 dog after 11 weeks caused no withdrawal symptoms. Increase of acetanilid in 3 other dogs to 400 (3 days) and 600 (4 days) mg/kg gave a methemoglobin peak of 65%. These levels of acetanilid administration resulted ultimately in reversible hypochromic anemia. There was drowsiness and analgesia, but no withdrawal symptoms. Tolerance did not develop since methemoglobin, lethal dose and the time of death corresponded to those of acute experiments (o.c.). Dogs killed during the chronic experiments showed earlier, bone marrow hyperplasia and reversible changes in the liver and, later, non-specific changes in the central nervous system, cortex and visceral organs (Hicks and Karczmar, to be published). Daily intraperitoneal administration to rats of $\frac{2}{3}$ of the lethal dose of acetanilid (up to 4 weeks) gave similar results with a methemoglobin peak at 35%. Withdrawal symptoms developed neither in dogs (contrary to Payne, o.c.) nor in rats independently of the administration schedule employed.

Duration of action of anticholinesterases in dogs. ALEXANDER G. KARCZMAR (by invitation) and THEODORE KOPPANYI *Dept of Pharmacology, Georgetown Univ School of Medicine, Washington, D. C.* Potentiation of pressor responses to

acetylcholine in atropinized dogs (pentobarbital sodium anesthesia) is used in this laboratory as a qualitative and quantitative assay of anticholinesterases (Science 106 492, 1947). This assay lends itself to establishing the duration of action of anticholinesterases (maximally potentiating doses used throughout) since the animal survives under test conditions for any desired time. It was found by means of this method that physostigmine and neostigmine are short-acting anticholinesterases with a duration of potentiation up to 6 hours. A thiophosphate type of anticholinesterase, 0-0-diethyl p-nitrophenol thiophosphate, belongs here also with a 5-hour duration of action (Anat Rec 101 89, 1948). A compound with an alleged specific action on pseudocholinesterase, dimethylcarbamate of (2-hydroxy-5-phenyl-benzyl) trimethylammonium bromide proved to be a short-acting (2 hours) true anticholinesterase. Organic phosphate esters are either long- or intermediate-acting. DFP belongs to the first category with complete extinction of potentiation of pressor effects after one week. Hexaethyl tetraphosphate (HETP) and tetraethyl pyrophosphate (TEPP), possibly active factor of HETP, cease to act after 12 hours. In all cases, anticholinesterase activity decreases rapidly at first and slowly after 50% of the effect disappears. Determination of anticholinesterase activity in terms of nicotinic effects of acetylcholine measures the biological reversibility of esterase inhibitors. It generally confirms the results obtained *in vitro* and seems free of errors due to dissociability of the esterase-anticholinesterase complex during *in vitro* procedures, (Goldstein J Gen Physiol 27 529, 1944).

Relation between chemical constitution and estrogenic action in a group of azomethines. H. H. KEASLING and F. W. SCHUELER (introduced by E. G. Gross) College of Pharmacy and Dept of Pharmacology, College of Medicine, State University of Iowa, Iowa City, Ia. This work is based on the working hypothesis that estrogenic compounds should consist of a relatively inert molecular structure with two active hydrogen-bond forming groups located at an optimum distance of 14.5 Å units (measured on Fisher-Hirschfelder-Taylor Atomic Models). Since the 4,4'-dihydroxy derivatives of stilbene ($-\text{CH}=\text{CH}-$) and azobenzene ($-\text{N}=\text{N}-$) (Schueler, F. W., Science 103 221 (1946)) show an estrogenic response, a study of the intermediate type of linkage as represented by the azomethines ($-\text{CH}=\text{N}-$) was carried out. In order to investigate the importance of variations in hydrogen-bond forming power, substitutions were made in the 4,4' positions of the basic structure, benzylidene aniline. All 16 possible combinations of the 4 substitution groups, hydrogen, hydroxyl, methyl, and methoxyl, were prepared and tested. The dihydroxy derivative best fulfills the requirements or

the hypothesis, the methoxy derivatives represent blocking of the hydrogen-bond forming groups, and the methyl and hydrogen substitutions are groups of low or no hydrogen-bond forming power. The estrogenic tests were carried out using ovariectomized rats, 4,4'-Dihydroxy benzylidene aniline produced a full estrogenic response in 12.5 mgm doses administered subcutaneously, and in 25γ doses intravaginally. None of the other derivatives produced an estrogenic response in 25-mg doses given subcutaneously. An investigation of other aspects of the general pharmacology of azomethines as well as the substitution of other ring linkages for the azomethine linkage in 4,4'-dihydroxy-diphenyl derivatives (e.g., $-\text{CO}-\text{NH}-$, $-\text{CH}_2-\text{O}-$, $-\text{SO}_2-\text{NH}-$, $-\text{CH}_2-\text{NH}-$, $-\text{S}-$, $-\text{S}-$, $-\text{CH}(\text{C}_2\text{H}_5)-\text{N}(\text{C}_2\text{H}_5)-$, $-\text{CO}-\text{CO}-$, $-\text{CH}(\text{OH})-\text{CO}-$, and $-\text{CO}-\text{O}-$) is now in progress.

Liver as the major organ involved in the detoxication of thiopental by the dog. A. R. KELLY (by invitation) and F. E. SHIDEMAN, Dept of Pharmacology, Univ of Michigan, Ann Arbor, Mich. Previous work from this laboratory, using *in vivo* methods, has established the liver as the major organ involved in the detoxication of thiopental in 3 animal species (mouse, rat, and man). *In vitro* experiments have also demonstrated the ability of both rat liver slices and mince to degrade this thiobarbiturate. Evidence presented here implicates the liver as the major site of detoxication of thiopental in the dog. One approach employed was a comparison of rate of disappearance from plasma of thiopental in normal dogs and in animals with reduced portal blood flow (Eck fistula). In both groups, plasma levels declined at the same rate for the first 8 minutes following injection of 20 mg/kg of the drug. At 2.2 mg % the curve for the Eck fistula animals leveled off and fell very gradually until the righting reflex was regained at 6½ hours at a level of 1.29 mg %. The normal curve dropped much more abruptly, the righting reflex returning 56 minutes after injection at approximately the same plasma level (1.2 mg %) as in the Eck fistula group. The second experimental method consisted of a comparison of plasma decay curves in the heart-lung, heart-lung-liver, and heart-lung-kidney preparation. The heart-lung preparation (morphine-chloralose anesthesia) showed a very gradually falling plasma thiopental curve, so that, after 70 minutes, approximately 25% of the drug had disappeared, over the same period of time, in the heart-lung-liver preparations, 2½ times as much was removed. Preliminary experiments indicate that heart-lung-kidney preparations may degrade thiopental to some extent although not nearly as rapidly as heart-lung-liver preparations.

Effects of podophyllotoxin and picropodophyllin on intact intestine and salivary secretion of non-

anesthetized dogs. MARGARET G. KELLY (by invitation), ALDO P. TRUANT (by invitation) and PAUL K. SMITH *Dept of Pharmacology, George Washington Univ School of Medicine, Washington, D C* A comparative study has been made of the pharmacological effects of podophyllotoxin and picropodophyllin (isomeric compounds obtained from podophyllin) on the intact intestine of non-anesthetized dogs, with Thiry-Vella fistulae. At the same time salivary secretion was investigated. The activity of the freed loop of the intestine was recorded by the classic rubber balloon and tambour method. Both compounds were injected intravenously in the form of a fine suspension in saline. Fifteen to 30 minutes after injection of 0.5 and 0.75 mg/kg of podophyllotoxin in dogs weighing 10 to 15 kg an irregular decrease in amplitude of contractions occurred, with a slight decrease in tone which at times increased. The rhythmicity of contractions remained normal. Normal gut activity returned in 3 hours at the above dose levels. At a dose of 5 mg/kg of picropodophyllin no effects were seen on the gut but salivation was increased. However, respiratory rate was intermittently interrupted by periods of dyspnea. When a dose of 7.5 mg/kg was used a regular increase in the amplitude of contractions was demonstrated with an increase in tone. In certain experiments intermittent quiescent periods occurred. In all the experiments with picropodophyllin, at the latter dose level, profuse salivation was seen which was blocked completely by 0.1 mg/kg of atropine. A dose of 0.5 mg/kg of atropine was not completely effective in blocking the gut effects of picropodophyllin. In a total of 20 experiments no catharsis was seen and no animals died.

Use of C^{14} in studies of metabolism of plant products. F. E. KELSEY *Dept of Pharmacology, Univ of Chicago, Chicago, Ill*. Some of the technical problems arising in a program of biosynthesis of radioactive drugs and their use in metabolic studies are discussed. A simple Geiger tube for the determination of the radioactivity of very weak samples is described. Briefly it consists of a bell-shaped tube, the open end of which is fitted with a sliding-tray arrangement for the insertion of the sample within the sensitive area of the counter. The counting gas, which flows continuously through the counter at atmospheric pressure, is helium saturated with ice-cold absolute alcohol. The available space on the sample holder is approximately 20 cm³. The absence of a window and the position of the sample permits the counting of all betaparticles escaping from the sample. High sensitivity is essential for this work because of the dilution of the C^{14} in the process of the biological synthesis of the drugs by the plant and the further dilution by the C^{12} of the experimental animal used for the metabolic studies. Methods of han-

dling the biological materials are given with illustrations from experiments on the metabolism of radioactive digitoxin.

Actions of calcium and tetraethylammonium ions on the rat diaphragm preparation. CHARLES J. KENSLE (introduced by McKen Cattell) *Dept of Pharmacology, Cornell Univ Medical College, New York City*. The rat diaphragm preparation stimulated through its phrenic nerve at rates of 5 or 30 per minute failed rapidly when placed in a calcium-free Ringer's solution but not when in potassium-, magnesium- or phosphate-free Ringer. The threshold concentration of calcium required for minimal activity varied from 1.5 to 6.5×10^{-4} M while that for maximum activity varied from 7×10^{-4} M to 1.2×10^{-3} M. High concentrations (2.5×10^{-2} M) of calcium depress activity. Tetraethylammonium bromide (TEA) has been found to substitute for calcium on a molar equivalent basis in restoring maximum activity in calcium-deficient solutions providing the calcium concentration has been adjusted to that required for minimal activity. TEA did not substitute for calcium at subthreshold levels and did not appreciably lower the calcium threshold. The sensitivity of the diaphragm preparation to the curarizing agents D-tubocurarine chloride (DTC) and dihydrobetaerythroidine HCl (HBE) was greatly increased by lowering the calcium concentration. Neostigmine was not an effective antagonist of DTC at low calcium concentrations. TEA antagonized the action of DTC and HBE and to a lesser extent the failure produced by acetylcholine following treatment with DFP. Triethylphenylammonium chloride showed slight antiscaric activity and calcium replacement value but triethylsulphonium iodide, triethylethanolammonium chloride, and dimethyldiethanolammonium chloride showed neither.

Reversible blocking action of DFP at the neuromuscular junction of the rat diaphragm preparation. CHARLES J. KENSLE and CHARLES BERRY (introduced by McKen Cattell) *Depts of Pharmacology and Anatomy, Cornell Univ Medical College, New York City*. A study of the action of DFP (diisopropyl fluorophosphate) on the rat phrenic nerve-diaphragm preparation (Bulbring, Brit J Pharmacol & Chemotherapy 1: 38, 1946) has shown that in low concentrations (5×10^{-5} M) it increased the response of the rat diaphragm to nerve stimulation at rates of 5 and 30/min, whereas higher concentrations (5×10^{-3} M) prevented the response. The high concentration of DFP caused failure within 2 minutes but this was readily reversed as long as one hour later. The bath temperature was 38°C. Measurement of the phrenic nerve action potential and the response of the diaphragm to direct stimulation localized this blocking action of DFP at the neuromuscular junc-

tion In the presence of low concentrations of DFP and after exposure to high concentrations, acetylcholine (1-2 micrograms/ml) 'curarized' the preparation The evidence obtained is inadequate to differentiate between the two most likely explanations for the reversibility of this block a) that the neuromuscular block produced by DFP is due to acetylcholine accumulation and that at least a functionally adequate amount of cholinesterase recovers its activity or b) that DFP in high concentrations possesses an action affecting neuromuscular transmission other than cholinesterase inhibition

Adrenolytic activity of a series of N-(9-fluorenyl)-beta-chlorethylamines JAMES KERWIN (by invitation), GLENN E ULLYOT (by invitation), EDWIN J FELLOWS, EDWARD MACKO (by invitation) *Research Div Smith, Kline and French Labs, Philadelphia, Penna, and Dept of Pharmacology, Temple Univ School of Medicine, Philadelphia, Penna* Substances with the following structure were compared with 'Dibenamine' for their effect after intravenous administration on the pressor action of epinephrine in cats anesthe-

R
|
R₁-N-CH₂-CH₂-Cl HCl

In all of the compounds R = the 9-fluorenyl radical Activity greater than that of 'Dibenamine' was noted only in the case of the compound in which R₁ was ethyl In those substances in which R₁ was methyl, propyl, isopropyl or secondary butyl, activity comparable with that of 'Dibenamine' was obtained The derivatives in which R₁ was n-butyl, isobutyl, n-amyl, isoamyl, n-heptyl, benzyl or phenylisopropyl were less active than 'Dibenamine'

Studies on radioactive digitoxin (*Digitals lanata*) T EUGENE KIMURA (by invitation) and E M K GELLING *Dept of Pharmacology, Univ of Chicago, Chicago, Ill* Radioactive digitoxin was biosynthesized by the incorporation of C¹⁴O₂ into *D lanata* by employing the method as reported by Geiling *et al* (Science 108 558, 1948) and by the concurrent use of a humidity-controller recently described (Science 108 560, 1948), while extraction of the glycoside was conducted in a manner substantially similar to that described by the authors Quantities of C¹⁴O₂, varying from a total of 600-1440 uc (300-180 uc/plant) were introduced in divided doses at suitable intervals into batches of *lanata* grown for 4-6 weeks Intensities of radioactivity from the crystallized glycosides in the order of 15,000 cpm/mg and 25,000 cpm/mg were registered from a 10-cm² surface, employing an internal Geiger counter (to be described elsewhere) when plants given 180 uc and 300 uc, respectively, were employed Preliminary studies on the perfused hearts of rats and guinea pigs indicate pres-

ence of higher levels of radioactivity localized in the ventricles than in the atria, the rat heart showing a greater degree of difference than the guinea pig Distribution studies have been carried out in the frog, guinea pig, and rat

Further studies on the pharmacology of adrenolysis THEODORE C KING (introduced by Theodore Koppányi) *Dept of Pharmacology, Georgetown Univ School of Medicine, Washington, D C* The hemodynamic responses of nembutalized dogs to epinephrine, DL-nor-epinephrine, and DL-N-isopropylarterenol (isuprel) (5-10 gamma/kg) were studied following administration of gradually increasing doses of yohimbine, benzylimidazoline (priscoll), dibenamine, and ergotamine Epinephrine effects are progressively decreased until complete abolition of the pressor response is obtained at the following dosage levels (mg/kg) yohimbine-0.75, priscoll-2.0, dibenamine-1.0 Reversal of epinephrine pressor effects does not occur until larger doses of these compounds are given (mg/kg) yohimbine-2.0, priscoll-10.0, dibenamine-10.0 Diminution but never complete inhibition or reversal of nor-epinephrine responses was observed with all doses cited Fifty per cent diminution of response to nor-epinephrine was observed with yohimbine-0.2, priscoll-0.4, dibenamine-3.0 (mg/kg) Isuprel effects showed 50% inhibition only following yohimbine (0.5 mg/kg) and priscoll (1.0 mg/kg) Isuprel effects were exaggerated by dibenamine Ergotamine tartrate (0.05 mg/kg or more) produced well over 100% potentiation of epinephrine and nor-epinephrine pressor effects Similar doses produced complete reversal of isuprel effects with pressor responses over 50 mm Hg Epinephrine responses potentiated by ergotamine are reversed only by larger than the minimum effective doses of priscoll or dibenamine

Pharmacological actions of two aliphatic amines THEODORE O KING (introduced by Theodore Koppányi) *Dept of Pharmacology, Georgetown Univ School of Medicine, Washington, D C* Cocaine HCl (5-10 mg/kg) administered intramuscularly completely abolishes or greatly inhibits pressor responses elicited by 2-methyl amino-6-hydroxy-8-methyl heptane (aranthol, Bilhuber-Knoll) (1.0-5.0 mg/kg) and by 2-methyl amino heptane (oenethyl, Bilhuber-Knoll) (0.02-0.10 mg/kg) In similar experiments in which dibenamine HCl (20 mg/kg) was used, complete abolition or marked (65-95%) inhibition of the pressor responses to aranthol and oenethyl were observed Cocaine was generally more effective than dibenamine in this respect so that when cocaine was used following dibenamine, further depression of the reduced responses were obtained In experiments in which dibenamine was used following cocaine, small pressor responses were

obtained with aranthol after dibenamine administration, even in cases where there had been complete abolition of pressor responses by cocaine. The effectiveness of aranthol in antagonizing hypotension due to spinal anesthesia (procaine) was tested in laminectomized dogs. Aranthol HCl (5 mg/kg) was administered after the mean arterial blood pressure fell to about 80 mm Hg. The injection of this amine produced pressor effects up to 50 mm Hg. The blood pressure then gradually fell to a level still 10 mm above the hypotensive minimum and remained at this level for 1½ hours. Aranthol was also effective in dilating the pilocarpine-constricted bronchial musculature. No tachypylaxis was observed when aranthol HCl (25 mg/kg) was injected intravenously at 5-minute intervals.

Heart sounds—electrostephone and recording machine (motion picture). HARRY KIRSCHBAUM (introduced by F. F. Yonkman) *Detroit, Mich.* This presentation deals with amplification and registration of cardiac sounds. It includes a description of the electrostephone and recording device. This device amplifies human fetal heart sounds and a permanent recording of the fetal and adult heart sounds can be made on wire, tape or film. By means of this instrument the response can be determined of both fetal and adult hearts to various pharmacologic agents. The machine has been used successfully in experimental research as well as in clinical surgery.

Cholinesterase as a cholinergic blocking agent. THEODORE KOPPANYI and ALEXANDER G. KARCZMAR (by invitation) *Dept. of Pharmacology, Georgetown Univ. School of Medicine, Washington, D. C.* Among the cholinergic blocking agents, atropine-like and curare-like drugs owe their activity to specific effects on acetylcholine receptors. They appear to act independently of the acetylcholine-cholinesterase chain reaction; in fact, some show an antiesterase rather than an anti-acetylcholine effect. The employment of a new purified, injectable, true cholinesterase (Special Chemicals Division, Winthrop-Stearns, Inc.) added a third type of cholinergic blocking agent to pharmacological technique (*Anat. Rec.* 101:36, 1948). This substance, upon intravenous injection, antagonizes both the muscarinic and nicotinic effects of injected acetylcholine in the intact mammal. The injection of cholinesterase into the turtle heart accelerates the rate and reverses other cholinergic effects obtained following the intracardiac injection of acetylcholine or of physostigmine. Cholinesterase injections, however, failed to prevent the cardiac effects of the faradic stimulation of the vagus. In cases where bradycardia produced by acetylcholine or physostigmine was abolished by cholinesterase, the vagus could not be paralyzed even by the intracardiac administration of massive

doses of this enzyme. The effect of cholinesterase on injected acetylcholine, and the comparative inefficiency of the enzyme in relation to vagus stimulation were observed also in dogs and cats. Unless it can be demonstrated that the enzyme does not penetrate to the site of acetylcholine liberation in the neuromuscular effector system, the above observation is of distinct theoretical significance.

Mechanism of action of anticholinesterase. THEODORE KOPPANYI *Dept. of Pharmacology, Georgetown Univ. School of Medicine, Washington, D. C.* Anticholinesterases potentiate the muscarinic and nicotinic effects of acetylcholine, the ganglionic effects of nicotine and the responses to cholinergic (including preganglionic) nerve stimulation. In larger doses they paralyze the sympathetic ganglia. This phenomenon is possibly independent of acetylcholine accumulation, because a) paralytic and antiesterase concentrations of individual drugs differ, b) nicotine pressor effects and pressor effects obtained on preganglionic stimulation are likewise abolished by paralytic doses of anticholinesterases, c) in some instances the paralytic effect of one antiesterase may be reversed by another, or even by the same anticholinesterase (*Science* 106:492, 1947). This latter effect may be related to the reversal by anticholinesterases of nicotine paralysis of autonomic (not solely sympathetic) ganglia. Antiesterases, however, differ in several respects from each other: a) Those of the physostigmine or neostigmine type prevent the pharmacological effects of DFP (intact animal). Acetylcholine pressor effects in atropinized and physostigminized animals are not further increased following administration of various doses of DFP. On the other hand, DFP and other phosphate esters have no such inhibitory effects on physostigmine or neostigmine, or on each other. b) The antiesterases differ as to potency, ganglionic paralytic dose, duration of action, and as to shape of curves, expressing the relationship between their concentration and the magnitude of the pressor effect of acetylcholine in atropinized animals. c) Some antiesterases appear to inhibit pseudo-cholinesterase but not true esterase. The assay of anticholinesterases used in this laboratory did not confirm this specificity. Their action is better explained in terms of the concept of 'essential cholinesterase' (*Milit. Res. Developm. Board* 4:271, 1948; *Bull. Johns Hopkins Hosp.* 83:532, 1948).

Pharmacologic and toxicologic data concerning diethylaminoethyl ester of 1-phenyl-cyclopentane-1-carboxylic acid hydrochloride (Parpanit). CHARLES P. KRAATZ (by invitation), CHARLES M. GRUBER, JR., HUBERT L. SHIELDS (by invitation) and CHARLES M. GRUBER *Dept. of Pharmacology,*

Jefferson Medical College, Philadelphia, Penna
 The LD₅₀ of parpanit has been determined as follows rabbits intravenously, 24.5 mg/kg, white mice intravenously, 45.1 mg/kg white mice intraperitoneally, 222.3 mg/kg, white rats intraperitoneally, 209 mg/kg. Toxic doses of the drug in these animals produce symptoms indicative of strong stimulation of the central nervous system, with death resulting ultimately from respiratory paralysis. In relatively non-toxic doses, parpanit has been found to have the following actions in experimental animals: a transitory vasodilatation independent of the central nervous system, a block of the terminal receptors of the parasympathetic-innervated structures rendering them insensitive both to nerve stimulation and applied acetylcholine, inhibition of activity of the intact intestine and depression of intestinal musculature, depression of the frog ventricle and excitation of the mammalian uterus. Comparative experiments have established that parpanit is similar qualitatively to traseratin which it resembles chemically, but is somewhat more active in inhibiting the intestine and in its parasympatholytic effect. Parpanit in the latter action is much less potent than atropine.

Effect of intravenous 'Tween' solutions in various animals and man JOHN C. KRANTZ, JR. and JOSEPH G. BIRD *Dept. of Pharmacology, Univ. of Maryland School of Medicine, Baltimore, Md*
 Polyoxyethylene derivatives of sorbitan esterified with fatty acids such as oleic, lauric and stearic, are used as dispersing agents for fatty substances under the name of 'Tweens'. We have observed that these substances when injected intravenously into dogs (in dilute solution) and other species of the canine family, produce a prolonged fall in blood pressure, which presumably is due to the release of histamine or some histamine-like substance. In other species of common laboratory animals this condition does not obtain, nor has it occurred in a limited number of tests in man.

Uptake of bromsulphthalein by the liver of the rat II. Studies with radioactive bromsulphthalein (BSP) JOHN KREBS (by invitation) and RALPH W. BRAUER *Dept. of Pharmacology and Experimental Therapeutics, School of Medicine, Louisiana State Univ., New Orleans, La*
 Bromsulphthalein containing S³⁵ has been prepared by the reaction of phenoltetrabromphthalein with H₂SO₄ containing S³⁵. The material has been purified by chromatographic adsorption, one milligram of the end product contains 0.1 millicurie of S³⁵. The rate of exchange with inorganic sulfate of the —S³⁵O₃ attached to the dye in aqueous solution, in tissue slice experiments, and *in vivo* is unimportant quantitatively if the experiments are completed within 3 hours or less, the exchange rate under these various conditions being of the order of 5% per hour or less. Radioactive BSP has been used in

a study of the release of BSP taken up by liver slices against very low concentrations of BSP in the circumambient fluid. Also the exchange of tagged BSP taken up by liver slices against various BSP concentrations in the medium has been studied. Results to-date indicate that the BSP taken up by liver slices falls into two fractions, one of which is released or exchanged at a rapid rate, while the second fraction, larger in amount, is released at a constant rate independent of the intracellular concentration. The dye was administered intravenously to a series of rats whose abdomen was prepared for quick laparotomy. Five minutes after the administration of the dye the livers were frozen by liquid air, transferred to a freezing microtome, and sections cut for radioautographic studies in a cryostat at -20°C. A stripping film technique was used for the preparation of the radioautographs. Results to-date confirm early conclusions that the uptake of BSP does not involve the Kupffer cells but proceeds directly from the plasma into the hepatic cells.

Quiescence preceding peristaltic constriction in the ileum HUGO KRUEGER *Dept. of Zoology, Oregon State College, Corvallis, Ore*
 Subcutaneous injection of morphine and its derivatives in adequate doses usually initiates peristalsis in Thiry-Vella loops of the ileum in dogs. Activity of the lower ileum was recorded once weekly from a Brodie bellows connected to a tandem, double-chambered, water-filled balloon inserted into the lumen of the loop. The pressure used to distend the chambers of the balloon was 31 cm. of water. Drugs were administered after a 100' control period. The advancing constriction of peristalsis, as described by Bayliss and Starling, is preceded by an advancing area of inhibition. In our experiments, the inhibition usually involved both a relaxation of the ileal muscle and a complete cessation of rhythmic contractions. Occasionally rhythmic contractions did not cease but were reduced in magnitude. The duration of the period of complete quiescence was 10 seconds or less in 731 out of 3057 measurements obtained from 2012 waves recorded during 536 experiments on 33 animals, 1453 waves had a period of complete quiescence between 10 and 30 seconds, 744 between 30 and 60 seconds and 129 were over one minute in duration. The longest period of quiescence measured was 290 seconds. Thus a quiescent period was questionable or negligible in 24% but was easily appreciable in 76% of the observations. The quiescence usually developed while the ileal muscle relaxed prior to the arrival of the advancing area of constriction but quiescence, prior to the arrival of the constricting ring, often occurred without relaxation of the ileal muscle, especially if the ileum was already nearly maximally relaxed.

***In vivo* action of morphine, urethane and pheno-**

barbital on the glycogen synthesis from glucose in the rat liver ERNEST KUN and L G ABOOD (introduced by E M K Geiling) *Dept of Pharmacology, Univ of Chicago, Chicago, Ill* Starved rats were injected with varying doses of morphine, urethane and phenobarbital one hour before glucose administration by stomach tube, and the liver glycogen and carbohydrate intermediates were measured 5 hours later. While normal starved rats synthesized an average of 36 mg glycogen/gm of liver in 5 hours after glucose administration, 100 mg/kg morphine or 1 mg/kg urethane completely inhibited glycogen deposition. Phenobarbital in 100 mg/kg doses produced 58% inhibition. The degree of inhibition was a function of the dose. Morphine proved to be the most potent inhibitor, 10 mg/kg causing 90% inhibition. Analyses for phosphorylated carbohydrate intermediates in drug-treated rat livers revealed a complete inhibition of esterification of inorganic P. Inorganic P was completely esterified in normal animals receiving glucose while none was esterified in the drug-treated ones. The quantitative distribution of the intermediates varied depending on the drug studied. A marked decrease in nucleoprotein phosphorus (0.1-0.2 mg/gm compared with the normal of 1.5 mg/gm) and phospholipid phosphorus (0.075-0.150 mg/gm compared with normal values of 0.9-1.1 mg/gm) was observed in the drug-treated animals.

Guanidine the agent responsible for the convulsive response to intracisternally injected streptomycin S KUNA (by invitation), F CUCHE (by invitation) and H MOLITOR *Merck Inst for Therapeutic Research, Rahway, N J* In an attempt to determine whether the convulsive response caused by streptomycin on intracisternal injection in rabbits was due to an intrinsic property of the streptomycin molecule, or to an impurity, the following investigation was undertaken. Testing individual components of this molecule indicated that guanidine was itself capable of causing this response. It was further demonstrated that streptomycin, streptidine or acetamidine caused like degrees of convulsive response when administered on the basis of their guanidine content. It was thus evident that the convulsive response produced by intracisternal administration is due to the guanidine content in the molecule. Impure streptomycin administered intracisternally on a unit basis caused more severe convulsions than the same amount of pure streptomycin similarly administered. Analyses of several lots of streptomycin of varying purity showed that on a unit basis, impure streptomycin contained a larger amount of guanidine than relatively pure streptomycin. When these lots were administered intracisternally in rabbits on the basis of their guanidine content, comparable convulsive responses were obtained. It is thus

evident that the extra guanidine present as impurity or as degradation products in low potency streptomycin is responsible for the greater convulsive response observed following intracisternal injection of such material.

Storage of DDT in the fat of the rat FRIEDA KUNZF (by invitation), A A NELSON, O G FITZHUGH and EDWIN P LAUG *Div of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D C* Answers to the following questions were sought: 1) Is there a level of DDT intake in the diet at which no storage in the fat occurs? 2) What is the relationship between length of exposure to DDT and storage in the fat? 3) How rapidly does DDT disappear from the fat after exposure is terminated? 4) What is the relation between age and rate of DDT accumulation in fat? 5) What is the lowest level of intake of DDT at which pathological changes may be seen in the liver? Answers to these questions are as follows: 1) Accumulation of DDT in the fat occurs at every level of intake down to and including 1 ppm. 2) With time, there is a progressive rise in storage, reaching a maximum at 23 weeks. This period of time necessary to reach maximum storage is independent of the level of intake within the range of 1-10 ppm. 3) Fifty per cent of the DDT store still remains after one month on a DDT-free diet, 25% after 3 months. 4) Comparison between groups of weanling and 1-month-old rats revealed identical rates of DDT accumulation, in spite of the fact that the consumption of DDT on a per kg body weight basis is considerably greater in the younger animals. 5) Evidence of liver injury has been noted in rats consuming diets containing 5 ppm DDT for 4-6 months.

Beryllium poisoning II One-year studies by intratracheal injection C W LABELLE, P MORROW, C BOOTH, F WESCOTT, G. MELVILLE (introduced by H C Hodge) *Dept of Radiation Biology, Univ of Rochester, Rochester, N Y* A study has been made on a total of 325 rats and 18 rabbits exposed to beryllium, with suitable controls, plus smaller numbers of mice, guinea pigs, monkeys and dogs. Each of these animals received beryllium by intratracheal injection, usually as an insoluble compound, at levels ranging from 5 to 100 mg Be/kg. Data are presented showing the resulting growth, mortality, hematology (10 variables), urine chemistry (15 variables), gross organ changes, organ weights (5 organs) and histological changes, and lung beryllium content over a period of one year after the injection. A chronic type of lesion developed in the lungs of most of the exposed animals which was consistent within a given species and for a given compound, although in no case identical with the human chronic lesion. During the same period, most of the commonly measured variables in the blood and serum remained normal.

The outstanding changes were increases in blood platelets and the absolute polymorphonuclear content of the circulating blood

Bronchodilator action of butanol derivatives

A M LANDS, O H SIEGMUND (by invitation) and ESTELLE ANANENKO (by invitation) *Biology Div, Sterling-Winthrop Research Inst, Rensselaer, N Y* Bronchodilator action was determined in isolated perfused guinea pig lungs. The doses, in micrograms, required to abolish histamine constriction were Butaneprine, 1-(3,4-dihydroxy-phenyl)-2-amino-1-butanol-120, isopropyl analog, 1-(3,4-dihydroxyphenyl)-2-isopropylamino-1-butanol HCl-50, cyclopentyl analog, 1-(3,4-dihydroxyphenyl)-2-cyclopentylamino-1-butanol HCl-10 epinephrine-5, Isuprel-15. Results obtained in guinea pigs with nebulized histamine are shown below

Drug	Dose mg/kg	Effect %
Butaneprine	0.5	78
Isopropyl analog	0.02	108
Cyclopentyl analog	0.05	116
Isuprel	0.01	118
Epinephrine	0.02	147

The cardiovascular action of these butanol derivatives is much weaker than that of Isuprel. The Isuprel ratios for action on heart rate were Butaneprine—300, isopropyl analog—30, cyclopentyl analog—60. If the bronchodilator action is compared with the effect on the heart rate, the greatest therapeutic margin is obtained with the cyclopentyl derivative and with the isopropyl derivative > Butaneprine. The most effective bronchodilator derivatives are effective spasmolytic agents for the intestine and uterus. Acute toxicity was determined by intravenous injection into albino mice. The LD₅₀ values in mg/kg were Butaneprine—117, isopropyl analog—57, cyclopentyl analog—84, epinephrine—27, Isuprel—77.

Alteration of the pH of the blood as a means of improving experimental cardiac anoxia KURT LANGE, VICTOR TCHERTKOFF, FRANK GRAIG and DAVID WEINER (introduced by M G Mulinos) *Dept of Medicine, New York Medical College, New York City* The anoxic pattern found in E K G's of dogs and rabbits following exposure to lowered oxygen tension in the inspired air or to cold environment can be reversed by the administration of acids lowering the pH. Moreover a shift of the blood pH to the acid side prevents the appearance of the anoxic pattern of the E K G of animals in an anoxia test. These effects are due to an increased oxygen dissociation with subsequent increase in oxygen available to the tissues. Normal animals do not show a change in their E K G pattern with lowering of the pH of the blood within reasonable limits. They do show an anoxic pattern in the

E K G when their blood is shifted to the alkaline side. Calcium, phosphorous, sodium and potassium do not play a role in the reversal of the anoxic E K G. The pH shifts required to produce beneficial effects need only be slight and appear to be well within the range of safety.

Electroshock seizures in the hamster and their modification by antiepileptic drugs EDWARD H LANPHIER (introduced by Carl C Pfeiffer) *Dept of Pharmacology, Univ of Illinois College of Medicine, Chicago, Ill* Application of electrical stimuli (60 cycle, 0.3 sec) via electrodes placed in the buccal pouches of the hamster proved rapid and advantageous in producing convulsions. Individual mean thresholds ranged from 25.0 to 50.5 ma with a mean of 36.5 ma. The average standard deviation in a series of daily determinations amounted to 6.3% of the average mean. The coefficient of correlation between weight and threshold proved to be +0.754, and useful predictions of threshold on the basis of weight could be made. Mortality in the hamster was 0.44% compared to 19% in the mouse. Clonic activity in maximal and sub-maximal seizures is much less prominent than in the mouse and rat, but modification of threshold and seizure pattern by antiepileptic drugs does not differ significantly. The hamster is thus a useful and convenient experimental animal for electroshock studies.

Effect of chemical configuration on the edema-producing potency (EPP) of acids, aldehydes, ketones and alcohols P S LARSON, J K FINNEGAN and H B HAAG *Dept of Pharmacology, Medical College of Virginia, Richmond, Va* The method used for measuring edema production is a modification of one that we have previously described (J Pharmacol 89:115, 1947). Morphinized male albino rabbits are tied in a supine position. A pocket is made of the right eye upper lid and kept filled with a solution of the irritant for 3 minutes. One hour later the rabbit is killed, the upper palpebral conjunctiva of each eye excised, weighed, dried and reweighed. The ratio of moisture to dry weight for each membrane is calculated and the difference between the ratios represents the degree of edema production. For each irritant studied, the molar concentration needed to produce a 2.5 unit increase in moisture to dry weight is determined. With monobasic organic acids, excepting formic, EPP increases with increasing molecular weight. Corresponding dibasic acids may have a lower EPP while unsaturation may increase EPP. HCl has no greater EPP than the more weakly ionized monobasic organic acids. With saturated aldehydes, excepting formaldehyde, increasing molecular weight results in increasing EPP. Unsaturation may markedly increase the EPP but this effect decreases with increasing molecular weight. Insofar as solubility permitted testing, it

appears that with ketones the EPP increases with increasing molecular weight. Among primary alcohols, EPP increases markedly with increasing molecular weight, decreases with unsaturation, and appears to be unaffected by isomerism. In passing from primary to secondary to tertiary alcohols, the EPP progressively declines.

Species variation in the protective action of anesthesia against the acutely lethal effect of nicotine. P. S. LARSON, J. K. FINNEGAN, J. CONWAY BIBB (by invitation) and H. B. HAAG, *Dept of Pharmacology, Medical College of Virginia, Richmond, Va.* The protective action of anesthetics against death from acute intravenous administration of nicotine was first noted by Franke and Thomas (*J Pharmacol* 48:199, 1933), who found that the smallest dose that was generally fatal for etherized dogs was 5 mg/kg as compared to 3 mg/kg for unanesthetized dogs. Subsequently Gold and Brown (*J Pharmacol* 54:463, 1935) found that after barbital slightly more nicotine is required to cause death in cats than in the normal animal, but that the increment is less than two-fold. In the present report, we have extended these observations to include other species. Male albino rabbits, rats and mice were used. Two intravenous LD_{50} determinations for nicotine were made on each species, one on unanesthetized and one on anesthetized animals. At least 3 groups of from 6 to 25 animals were used in each determination. The rabbits were anesthetized with sodium amytal (45 mg/kg, intravenously), the rats and mice with dial (60 and 100 mg/kg respectively, intraperitoneally). The results are summarized in the

(SY28) have been studied in rabbits. The drugs were applied to rectangular areas (1.25 x 12.5 cm) of the skin of the abdomen and repelled through the skin by a current density of 0.33 milliamperes/cm² applied for 5 minutes. SY 28 was applied in total doses of 0.02-0.4 mg, whereas Dibenamine was used in doses of 0.4-1.6 mg so as to produce equivalent blocking. The intensity of vasoconstriction following the intracutaneous administration of epinephrine (1:1000-1:40,000) was used as the indicator mechanism to reveal adrenergic blocking activity. The penetration of both SY-28 and Dibenamine was expedited by ion transfer and resulted in adrenergic blocking action at significantly lower dosage levels. SY-28 was found to be 10 to 20 times as potent as Dibenamine under the conditions of these experiments. Evidence of the epinephrine-reversal phenomenon has been noted in the rabbit skin following the local or intravenous administration of both SY-28 (0.1-4.0 mg/kg) and Dibenamine (4-32 mg/kg). These observations reveal the presence of vasodilator fibers in the skin of the rabbit.

Chronic toxicity of phenylmercuric acetate and mercuric acetate in the rat. EDWIN P. LAUG, O. G. FITZHUGH, FRIEDA KUNZE (by invitation), and A. A. NELSON, *Div of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D. C.* At the end of a 2-year feeding experiment, in which phenylmercuric acetate and mercuric acetate were fed to rats at levels of 0.1 ppm to 160 ppm mercury in the diet, the following observations were made: 1) Phenylmercuric acetate is considerably more toxic than mercuric acetate on the basis of mortality and growth effect. Thus reduction in growth was noted on 10 ppm phenylmercuric acetate, but only at 160 ppm mercuric acetate. 2) Diets containing phenylmercuric acetate in the range of 0.5 to 10 ppm mercury, support approximately 20 times the storage of mercury in the kidney than comparable levels of mercuric acetate. 3) Phenylmercuric acetate produced gross effects on the kidneys, such as pitting and hypertrophy. These effects were evident at dietary levels as low as 2.5 ppm. 4) Injury to the kidney tubules, more pronounced in the females than the males, could be demonstrated at a level of 0.5 ppm for phenylmercuric acetate. This was $\frac{1}{10}$ of the level of mercury intake at which comparable damage could be demonstrated with mercuric acetate. 5) Urinary excretion studies show that on diets containing phenylmercuric acetate the excretion of mercury is 10 to 20 times greater than that on diets containing mercuric acetate. Conversely, the fecal excretion with mercuric acetate is 3 times as great as with phenylmercuric acetate. These facts are taken to indicate that the increased toxicity of phenylmercuric acetate arises from its superior absorption into the organism.

Species	$LD_{50} \pm S.E.$ for nicotine (mg/kg)	
	Unanesthetized	Anesthetized
Rabbit	5.9 \pm 0.6	9.4 \pm 0.2
Rat	2.8 \pm 0.3	27.5 \pm 1.7
Mouse	0.55 \pm 0.01	7.1 \pm 0.7

accompanying table. In rabbits, anesthesia raised the LD_{50} value for nicotine about 60%, which is in keeping with the slight increase reported for dogs and cats. However, in rats and mice, anesthesia elevated the LD_{50} values 10- and 13-fold respectively. Thus a marked species variation exists in the protective action of anesthesia on the acutely lethal effect of nicotine.

Cutaneous administration of adrenergic blocking agents by ion transfer. JULES H. LAST, ARTHUR A. RODRIGUEZ (by invitation), and ISADORE PITESKY (by invitation), *Depts of Pharmacology and Physical Medicine, Univ of Illinois College of Medicine, Chicago, Ill.* The local adrenergic-blocking effects of N,N-dibenzyl- β -chloroethylamine (Dibenamine) and N-ethyl-N-(1-naphthylmethyl)- β -bromoethylamine hydrobromide

A practical classification system for drugs C D LEAKE *Pharmacology Laby, Univ of Texas Medical Branch, Galveston, Texas* Aristotle emphasized the importance of classifying diverse concepts as a necessary prerequisite to their systematic consideration. Classification is accomplished logically by abstraction and analogy. Neither of these has been encouraged in the properly skeptical and critical development of modern experimental biology and medicine. With the tremendous accumulation of diverse factual concepts in such a science as pharmacology, a working classification is becoming increasingly necessary if the science is to be successfully taught or further explored. A classification of drugs on a chemical basis is not at present practical because the relationship between chemical constitution and biological activity is not yet satisfactorily developed, and does not broadly relate to the primary purposes of drugs. Such a classification of drugs as might be based on localization of biological activity, as proposed by H H Meyer, and later by Lamson, is also impractical because it is overly complicated, repetitive, and confusing in clinical practice. Indeed, the most satisfactory practical drug classification is one based on their chief use as a result of direct cumulative clinical experience. Such a classification is pedagogically helpful as has been well shown wherever it has been tried. It affords a systematic arrangement which aids the clinician and the researcher who may be trying to develop new drugs of clinical value or to improve on those already in use. Such a classification would conveniently follow clinical concepts in 1) drugs used mostly for diagnosis of disease, such as halogenated phenolphthaleins for liver function tests, 2) those directed most commonly to the prevention of disease, as vitamins, antiseptics, insecticides and rodenticides, 3) those employed primarily for the cure of disease ('chemotherapy'), as quinine in malaria and penicillin in syphilis, and 4) those drugs ordinarily found helpful in the alleviation of the symptoms of disease. For further convenience the latter may be subdivided into groups on the basis of the chief systems of the body involved with respect usually to stimulation or depression. Within these general groups further classification may advantageously be made on the basis of the mechanism of the biological action of the drugs concerned.

A warm wire analgesimeter R E LEE (by invitation), H L WILLIAMS (by invitation), and CARL C PFEIFFER *Dept of Pharmacology, Univ of Illinois College of Medicine, Chicago, Ill*. A simple apparatus to produce graded painful stimuli has been constructed. It consists of a stimulating point made of a 7 cm length of 26-gauge nichrome wire, bent in half to form a sharp-angled tip, connected in series to a dry cell and a potentiometer of 2 ohms resistance and a D C ammeter graduated

in 0.02 amperes reading up to 1.5 amperes. The temperature of the tip of the wire at ammeter readings of 0.4 to 1 has been calibrated with a thermocouple. Increases of 0.05 amperes result in an increase in temperature of 3 to 4°C. A temperature of 50°C constitutes a painful stimulus for most individuals. By use of the stimulator on the forehead it has been possible to determine the rise in pain thresholds in human subjects treated with analgesic drugs. The instrument has also been used successfully to determine the degree of analgesia produced by morphine sulfate (5 mg/kg) in mice. More quantitative results are obtained by this device than by the usual tail-pinch method. The device is also of teaching value to demonstrate delayed pain and to test for the duration of action of local anesthetics.

Pharmacology of thiomerin ROBERT A LEHMAN and E E KING (by invitation) *Dept of Therapeutics, New York University College of Medicine, New York City*. Thiomerin (di-sodium salt of N-[gamma-carboxymethylmercaptomercuri, beta-methoxy] propylcamphoric acid) is a mercurial diuretic obtained by replacement of the theophylline in mercuzanthin (Mercuriophylline, U S P XIII) by sodium mercapto-acetate to give a compound of the $-\text{CH}_2-\text{Hg}-\text{S}-$ type rather than $-\text{CH}_2-\text{Hg}-\text{N} <$. It was previously shown that in thiomerin (MT6) the acute cardiac toxicity characteristic of the conventional theophylline-bearing diuretics has been virtually eliminated at least with respect to the anesthetized cat (Proc Soc Exper Biol & Med 64 428, 1947). The present report concerns other pharmacologic properties of thiomerin as contrasted with presently used drugs. Intravenous lethal doses in the mouse have been estimated for thiomerin, mercuzanthin, mercurhydrin and salyrgan-theophylline and were found to be of the same order of magnitude when observed over a 4-day period. However, within the first half hour after injection, thiomerin is approximately $\frac{1}{10}$ as toxic as the other 3 drugs. Similar ratios were obtained using the Langendorff isolated cat heart. Absorption was estimated by analysis of injected muscle in rabbits and the absorption curve for thiomerin appears to resemble closely the curves previously reported for mercuzanthin and salyrgantheophylline (J Pharmacol & Exper Therap 62 26, 1938). The rate and completeness of excretion of mercury after administration of the diuretics was studied in cardiac patients. No striking differences were found. Storage of mercury in the kidney and liver after chronic administration in experimental animals has also been investigated. Data will be included on the fate of the sulfhydryl group as well as that of the mercury and a mechanism will be suggested to explain the pharmacologic activity of a mercurial diuretic in which

dissociation has been suppressed by mercaptide formation

Relative merits of commonly used sulfonamide drugs as components of mixtures DAVID LEHR *Dept of Pharmacology, New York Medical College, Flower and Fifth Avenue Hospitals, New York City* At a daily dosage of less than 4 gm, even the 'worst offender' sulfathiazole did not usually produce sensitization (D Lehr, Brit Med J 2 543, 1948) It follows that the renal protection of sulfonamide mixtures could be enhanced without the danger of increasing the incidence of allergic reactions, by using additional components in proportionately smaller amounts It can be assumed as established that, at present, sulfadiazine and sulfamerazine qualify for first and second place, respectively, as mixture components Sulfathiazole, sulfapyrazine, sulfamethazine and sulfacetimide deserve attention as possible 3d or 4th members Sulfathiazole was eliminated from the U S P because of its high clinical toxicity However, mixtures containing partial amounts of this drug demonstrated a low overall toxicity Sulfapyrazine, most insoluble of all compounds, induces frequent renal and allergic reactions and therefore offers no advantages over sulfathiazole Sulfamethazine possesses adequate solubility and low toxicity but is subject to substantial conjugation and plasma binding which diminish its therapeutic efficiency Sulfacetimide retains the high solubility of sulfanilamide and shares with the parent compound the improbability of renal concretum formation and the ready diffusibility into all tissues It shows low figures for conjugation, plasma binding and sensitization Recommended primarily against ocular and urinary infections, this drug demonstrates satisfactory bacteriostatic activity against a variety of human pathogens and gives good blood levels in man In experimental animals, sulfacetimide proved about 5 times less toxic than sulfadiazine The mixture sulfadiazine-sulfamerazine-sulfacetimide (equal amounts) revealed low toxicity in animals as well as excellent bacteriostatic activity *in vitro* and in experimental infections of mice After oral administration, blood and spinal fluid levels were similar to those from equal doses of sulfadiazine or sulfamerazine Preliminary clinical trials including several cases of pneumonia and two cases of penicillin resistant septicemia gave highly satisfactory results

Sodium phthalyl sulfacetimide A new gastrointestinal antiseptic DAVID LEHR *Dept of Pharmacology, The New York Medical College, Flower and Fifth Avenue Hospitals, New York City* Sodium phthalyl sulfacetimide (di-sodium N¹ acetyl N¹ phthalyl sulfanilamide di-hydrate) possesses good bacteriostatic activity against coliform organisms *in vitro* and in man In addition it displays satisfactory activity against many bacterial patho-

gens of the intestinal tract, especially the Shigella group (H Seneca and E Henderson, personal communication) The compound is readily water soluble and stable in the alkaline range of the body Spontaneous hydrolysis at the N¹ group remains negligible down to a pH of 6.0 A 20% aqueous solution of the drug has a pH of 7.30 After oral administration in rabbits, sodium phthalylsulfacetimide was present in aqueous solutions of 1500 to 3000 mg % strength in the small and large intestines, whereas the equimolar amount of sodium sulfadiazine, as representative of absorbable sulfonamides, was dissolved in the enteric contents only to the extent of 70 to 400 mg % Yet absorption of sodium phthalylsulfacetimide into the blood stream was minimal although it diffused readily into the deeper strata of the intestinal wall and produced at this site concentrations more than twice as high as the equimolar dose of sodium sulfadiazine From parenteral routes of administration in rabbits and rats sodium phthalylsulfacetimide readily entered the blood stream and was rapidly eliminated by the kidneys, causing high urinary concentrations The intraperitoneal toxicity was surprisingly low (approximate LD₅₀ for albino rats being 10 gm/kg body weight) In man a single oral dose of 10 gm sodium phthalylsulfacetimide did not produce any demonstrable blood levels and only about 1% of the dose appeared in the urine within 24 hours Therapeutic trials in acute gastrointestinal infections seemed encouraging and deserve further exploration

Tolerance in rats to new synthetic analgesic drugs JOHN R. LEWIS (introduced by A. M. Lands) *Biology Div, Sterling-Winthrop Research Inst, Rensselaer, N. Y.* The development of tolerance to the analgesic action of morphine and several compounds chemically related to Demerol or methadone was followed in rats The compounds investigated and respective doses used were morphine sulfate (10 mg/kg), 1-methadone hydrochloride (2 mg/kg), 1-isomethadone hydrochloride (3 mg/kg), ketobemidone or 1-methyl-4-(3-hydroxy-phenyl)-4-piperidyl ethyl ketone hydrochloride (3 mg/kg) and a sulfone derivative, 1-ethyl 1,1-diphenyl-3-dimethylaminobutyl sulfone hydrochloride (3 mg/kg) Data from a group of 20 rats were obtained for each compound These rats were given daily subcutaneous injections for 6 weeks and their analgesic reactions and body weights determined Tolerance developed most rapidly to the sulfone derivative and least to 1-isomethadone The development of tolerance to all the other compounds was quite similar and at the end of 6 weeks of daily administration the analgesic response was found to be only about 40% of the initial value As tolerance developed there was a decrease in duration of action which was probably related to the decrease in maximum effect There

was a general change in the character of the side-effects from depression to excitation following drug injection during the development of tolerance. After withdrawal, the only symptom observed was hyperexcitability which reached its maximum in about 48 hours. Recovery from the tolerance was least with ketobemidone and the sulfone derivative. With the other compounds, responses of about 90% of normal were obtained at 3 weeks after withdrawal. The daily administration of these compounds caused a decreased rate of growth which was probably due to a decrease in food consumption. Morphine caused the greatest and ketobemidone the least retardation of growth.

Screening test for radiopaque drugs. A. LIGHT (by invitation), P. B. DEWS (by invitation), J. TORNABEN (by invitation), E. H. LANG (by invitation), STATA NORTON (by invitation), and EDWIN J. DE BEER. *The Wellcome Research Labs., Tuckahoe, N. Y.* The methods currently used for the screening of compounds as possible cholecystographic agents usually require comparatively elaborate experiments on such animals as rabbits or dogs. Consequently, only limited numbers of animals may be studied. A convenient test employing the albino mouse has been developed. This test permits the use of large numbers of animals and the technique is simple because the mouse gall-bladder is not embedded in the liver and may be removed easily. Furthermore, only small amounts of drug are required. In performing the test, groups of mice are dosed orally with the drug being studied and, after a suitable time interval, are anesthetized with Evipal and killed. The gall-bladders are removed, pooled and dissolved in alkali, and the iodine is determined chemically. Dosage-response curves with standard drugs were obtained and the test has been employed for routine assays. The method has been adapted to other problems such as the screening of iodinated compounds for possible pyelographic properties.

A method for rapid graphic solution of time-percentage effect curves. JOHN T. LITCHFIELD, JR. *Chemotherapy Div., Stamford Research Labs., American Cyanamid Company, Stamford, Conn.* A method for rapid graphic solution of time-percentage effect curves has been developed. The method is derived from the provisional graphic solution described by C. I. Bliss (*Annals Applied Biol.* 24: 815, 1937). In his method, times are converted to logarithms and cumulative percentage effects to probits. These data are plotted, a straight line fitted by eye, and the parameters and errors of the line obtained by means of formulae given. Although this method of solution is relatively easy in the case of a complete curve (all individuals reacting), it becomes much more difficult when the curve is incomplete due to failure of some individuals to react. In the new method, which uses the data in

original form, and thus avoids the log-probit transformation, the data are plotted on logarithmic-probability paper, a straight line is fitted and the parameters are obtained from this line. Confidence limits of the parameters for 19/20 probability are obtained without computation by means of nomographs. When the curve is complete, only one of the nomographs is needed but when the curve is truncated, two additional nomographs are used. A complete solution may be made in any case in less than 5 minutes, without the use of a slide rule or calculating machine. The results are equivalent in all respects to those obtained by the more complex basic method. The method and nomographs are presented with several examples of their use.

Comparative toxicities of five substituted glycerol ethers. PRUDENCE C. LOEB (introduced by Charles H. Hine). *Div. of Pharmacology and Exptl. Therapeutics, Univ. of California Medical School, San Francisco, Calif.* Systemic toxicity after intragastric, respiratory and percutaneous absorption and topical effects from application to the eye and skin, and sensitization of skin were studied. The acute, intragastric LD₅₀'s (ml or gm/kg) in inbred white mice were: α -Ethyl (I) 9.35 ± 0.134 , α -Isopropyl (II) 8.2 ± 0.135 , α -Allyl (III) 4.2 ± 0.084 , α -Phenyl (IV) 2.65 ± 0.025 , α, γ -Diisopropyl (V) 1.86 ± 0.058 . Loss of righting reflex followed by reversible muscular paralysis was noted with all the compounds. Non-paralyzing doses produced no sensory depression. Death followed depression of respiration, probably of central origin. The vapor pressures are extremely low, and exposure of mice to vapor-saturated air at room temperature 8 hours daily for 10 days produced neither irritation nor significant mortality. Mist exposure for one hour produced slight temporary respiratory irritation in hamsters. Only V produced systemic toxicity after cutaneous application. II produced mild primary irritation of intact shaved rabbit skin and moderately severe irritation of abraded skin, III and V caused mild primary irritation of abraded skin. Both alcohol and glycerine produced greater irritation. V caused mild erythema of rabbit skin after seven daily applications of 2 ml/kg. Twenty such applications of I, II, and III were not irritating. Similar applications of 10 ml/kg (5% aqueous solution) of IV discolored the skin of rats, but did not cause irritation. II and V each caused mild transient irritation when instilled into the rabbit's eye, III caused moderate irritation. Guinea pigs were not sensitized by any compounds. The acute toxicity of the glycerol ethers is greater than that of the glycols.

Comparison between individual sensitivities to histamine and to diphenhydramine. S. LOEWE, L. A. WOODBURY (by invitation) and SUSANNE LOEWE PUTTUCK (by invitation). *Depts. of Phar-*

macology and Physiology, Univ of Utah School of Medicine, Salt Lake City, Utah When male guinea pigs inhaled nebulized histamine under uniform conditions, individuals differed little in 'histamine time' (T_H = inhalation time to a set endpoint) In 3 populations totaling 228 guinea pigs, mean T_H s were 79, 80 and 83 seconds, with coefficients of variation (C V) of 12, 23 and 17% T_H did not vary consistently with body weight When, however, the I P D₅₀ of diphenhydramine [median individual preventive (intraperitoneal) dose prolonging T_H to 390 seconds in 50% of experiments] was determined, individuals varied greatly (mean I P D₅₀ of 75 animals 66 mg/kg, C V 68%) Variation with body weight was also great, with body weights increasing from 230 to 550 gm, mean I P D's rose from 2.6 to 8.9 mg/kg In contrast, each individual's dose-response curve approximated an all-or-none curve 1) Sensitivities to histamine and to the antihistaminic are incongruous, this challenges the assumption of the same receptor substance for agonist and antagonist 2) Each individual is constant, but different individuals vary greatly in diphenhydramine response This strongly advocates the use of intraindividual methods (Science 106:89, 1947) of antihistaminic potency evaluation, to avoid the large standard errors of the group P D₅₀ assays For example, in intraindividual assays, C V's of the potencies (diphenhydramine = 1.0) of tripeleminamine (5.18), C-5581 H (1.75) and Antistin (0.48) were 2.7, 5.4 and 4.8%, respectively

Circulatory and other actions of sparteine in mammals Go Lu (introduced by P J Hanzlik) *Dept of Pharmacology and Therapeutics, Stanford Univ School of Medicine, San Francisco, Calif* The predominant effects of sparteine sulfate (5-20 mg/kg) intravenously in anesthetized (pentobarbital or morphine ether) and atropinized dogs and cats were bradycardia, sustained fall of blood pressure (varying with dosage), absence of central vasomotor depression Doses of 1 mg/kg sometimes caused fleeting opposite cardiac and blood pressure effects Subcutaneous, intramuscular and gastric administrations caused typical circulatory effects but the doses were higher Accordingly, sparteine is a direct cardiac depressant in mammals as in amphibia Electrocardiographically in unanesthetized dogs, the changes were typically quinidine-like Typical antifibrillation was demonstrated mechanically and electrocardiographically in anesthetized dogs with 0.5-1.0 mg/kg sparteine intravenously in auricular fibrillation produced by applying methacholine to the sinus node and slightly pinching the right auricle, higher doses (3-5 mg/kg) were required to arrest or prevent electrical fibrillation Other effects observed were slight reduction in excitability of vag and no antagonism of acetylcholine or metha-

choline (sparteine 5-10 mg/kg), fleeting depression of phrenics, prompt respiratory failure, the cause of death after 30-50 mg/kg intravenously (anesthetized dogs) Sparteine seems to be disposed of in the liver, corresponding circulatory effects requiring 3 to 5 times the dosage in the splenic vein compared with saphenous vein injection Brodie's methyl orange method adapted to estimating sparteine in the blood (sensitivity 1 gamma/cc) showed presence of the alkaloid for 2½ hours in the blood of dogs receiving 20 mg/kg intravenously, thus suggesting a comparatively slow escape from the circulation

Color and crystal tests for the identification of methadon and isomethadon G H W Lucas *Dept of Pharmacology, Univ of Toronto, Toronto, Canada* Special reagents for the rapid colorimetric identification of methadon as the free base and as salts, and of isomethadon, have been prepared by combining 90% sulphuric acid solutions of some heavy metals (copper sulphite 1%, gold chloride 1%, palladium oxide 0.3%) and an 0.5% solution of ammonium vanadate in concentrated sulphuric acid These metal solutions, which keep well, are combined in proportions of 8 to 1 with ammonium vanadate solution, which also keep well, the test solutions are useful for several hours only A useful solution which will keep about a day may be made by mixing the ammonium vanadate solution and Marquis reagent in the ratio of 1 to 2 Powdered ferric sulphate added to the ammonium vanadate solution, when freshly made, is a useful reagent The maximum sensitivity is reached with the gold and palladium reagents as one µg of methadon may be detected Many other salts of alkaloids, glycosides, barbiturates, antipyretics and antihistamine substances have been studied to determine any interference A reagent containing 1 gm of $\text{HAuCl}_4 \cdot 3\text{H}_2\text{O}$ and 9.4 cc of 55-58% HI solution appears to be the most sensitive for giving characteristic crystals with methadon (1:16,000) A 5% mercuric chloride gives very good and characteristic crystals but not so sensitive (1:4,000)

Local anesthetic action of some thiazolidone derivatives F P LUDUENA and JAMES O HOPPE (by invitation) *Biology Div, Sterling-Winthrop Research Inst, Rensselaer, N Y* The local anesthetic activity of several substituted 2-phenyl-(3-alkylamino or 3-dialkylaminoalkyl)-4-thiazolidone compounds has been investigated by one or more of the following tests sciatic nerve block (guinea pig), infiltration around the external canthus (rabbit), corneal instillation (rabbit), intradermal wheal (man) and spinal anesthesia (rabbit) With the diethylaminoethyl side chain the 3,4-methyl-enedioxyphenyl substituted compound (WIN 2125) was the most active (external canthus test) in comparison with analogs possessing the following phenyl substitutions 4-methoxy,

3,4 dimethoxy, and 3,4,5-trimethoxy WIN 2125 was as active and as toxic as procaine. The p-amino-phenyl analog is inactive. In the alkylaminoalkyl series the activity is greater. Two of these compounds, WIN 2661 (2-(3,4-methylenedioxyphenyl)-3-isobutylaminopropyl-4-thiazolidone) and WIN 2663 (the cyclohexylaminoethyl analog) have been studied more extensively. These two compounds are 4-5 times more active than procaine in producing nerve block and spinal anesthesia. Intradermally in man they are more than 5 times more active than procaine. Topically, on the rabbit cornea, they are less active than cocaine. Tissue irritation of these compounds is low, intradermally in rabbits, WIN 2661 and WIN 2663 in a 1% concentration produced mild and moderate irritation respectively (trypan blue test). No signs of irritation were observed in man after the intradermal injection of 0.5% solutions of these compounds. The respective values (in mg/kg) of WIN 2661 and WIN 2663 are as follows: mice, intravenously— 40 ± 1 and 30 ± 1 , subcutaneously— 320 ± 30 and 190 ± 10 , guinea pigs, intravenously— 20 ± 1 and 17.5 ± 1 .

Thromboplastic properties of some antiluetic drugs DAVID I. MACHT *Dept of Pharmacology, Labys of Sinai Hospital, Baltimore, Md*. The writer has already called attention to the fact that certain drugs, widely employed in medical therapeutics possess thromboplastic properties which may precipitate thrombo-embolic accidents. Among those studied experimentally were digitals, mercurial diuretics and the antibiotics penicillin and streptomycin. The author wishes to report now a new group of drugs which in animal experiments were found to shorten coagulation time of whole blood as tested by the Lee and White method. These are the antiluetic drugs arsphenamine, neo-arsphenamine, mapharsen, bismarsen, bismuth salicylate and sodium-bismuth-tartrate. All of these were studied on rabbits and cats, with and without general anesthesia, and administered either by intravenous or intramuscular injection. They all exhibited marked thromboplastic effects. A remarkable exception is Thiobismol, which exerts very little influence on coagulation time. The organic mercury compounds, mercurochrome, merodicein, and merthiolate on intravenous injection also hastened coagulation, and even small doses of HgCl_2 had the same effect. So did tryparsamide, and the widely employed new antisiphilitic, penicillin. The above properties of antiluetics should be borne in mind, in analyzing the causes of occasional grave reactions occurring in the course of antisiphilitic therapy.

Observations on several cyclohexyl- and phenyl-alkyl-amines EDWARD MACKO (by invitation) and EDWIN J. FELLOWS *Dept of Pharmacology, Temple Univ School of Medicine,*

Philadelphia, Penna. In the present studies, the pharmacological actions of 1-Cyclohexyl-2-amino-propane (S-10) and 1-Cyclohexyl-2-methylamino-propane (S-25) the N-methyl modification of S-10, have been compared with their corresponding phenyl analogues. Observations in rats, rabbits and guinea-pigs disclosed the fact that the cyclohexyl derivatives were decidedly less active central nervous system stimulants than their corresponding phenyl modifications. The cardiovascular action of the present compounds has been analyzed and their relative acute toxicity determined in three species of animals. Subacute toxicity studies also were carried out on the cyclohexyl derivatives.

Fate of pentothal in man LESTER C. MARK (by invitation), PHILIP A. LIEF (by invitation), E. M. PAPPER (by invitation), E. A. ROVENSTINE, ELEANORE BERNSTEIN (by invitation), and BERNARD B. BRODIE *Depts of Anesthesia and Biochemistry, New York Univ College of Medicine, and New York Univ Research Service, Goldwater Memorial Hospital, New York City*. A method was devised for estimating pentothal in biological material. This method is specific in that it does not include metabolic products of the compound in the measurement. The physiological disposition of the drug was studied. Negligible amounts of pentothal are excreted unchanged indicating that it is almost entirely transformed in the body. The drug metabolizes more slowly (about 15% per hour) than hitherto thought. The rapid recovery from anesthesia after the administration of small doses represents a shift of pentothal from plasma to tissues, rather than a rapid breakdown of the drug. Pentothal is extensively localized in various tissues of the dog. The tissue reservoir of pentothal may account for the long-lasting anesthesia obtained after the termination of sustained administration. The plasma concentration of pentothal is a function of plasma pH. Decreasing the pH to 6.8 in dogs by carbon dioxide inhalation lowered the pentothal level by about 35%, while increasing the pH by NaHCO_3 infusion to 7.6 produced a less striking change in the opposite direction. These changes were reversed when the pH was restored to normal. Evidence was found in human subjects of an acute tolerance to pentothal. Subjects maintained at high plasma concentrations of the drug awakened at higher plasma levels than those maintained at low plasma concentrations. Two transformation products have been isolated from urine. One of these has been purified and tested for anesthetic activity in mice. It has at most a mild sedative action.

Synthetic curare compounds IV N-Methyl-berbamine iodide and N-methyl-isotetrandine iodide DAVID FIELDING MARSH and DONALD A. HERRING (by invitation) *Dept of Pharmacology, West Virginia Univ School of Medicine, Morgan-*

town, W Va Berbamine was isolated from *Berberis vulgaris*. The curariform activity of its derivatives, N-methyl-berbamine iodide (MB), and N-methyl-isotetrandine iodide (N-methyl-O-methyl-berbamine iodide or MI), was determined in comparison with the corresponding isomers, d-tubocurarine chloride pentahydrate (dT), and d-O-methyltubocurarine iodide trihydrate (MeOdT). Structurally the berbamine derivatives

	dT	MeOdT	MB	MI
	mg/kg of body weight			
Albino rats				
LD ₅₀	0.27	0.032	0.40	0.77
Rabbits				
Head drop 50	0.125	0.016	0.125	0.28
Holaday head drop	0.15	0.02	0.15	0.35
Cat gastrocnemius muscle				
Equivalent paralysis	0.125	0.02	0.125	0.30
Dog head drop (3')	0.16	0.02	0.17	0.48
Man head drop (3')	0.15	0.03	0.18	

differ from the d-tubocurarine compounds in that the tetrahydroisoquinoline rings are adjacent instead of being separated by the oxybenzyl groups. Although the berbamine derivatives are not as potent as the d-tubocurarine compounds, the lack of even the minor undesirable side effects possessed by d-tubocurarine make their clinical investigation seem reasonable.

Further data on the feeding of beryllium salts to laboratory animals. E. A. MAYNARD (by invitation), W. L. DOWNS (by invitation), J. K. SCOTT (by invitation) and H. C. HODGE, Dept. of Radiation Biology, Univ. of Rochester, Rochester, N. Y. Data obtained from larger groups of rats (10 males and 10 females) fed beryllium sulfate and beryllium carbonate at a dietary level of 5% confirmed data from small groups (2 males and 2 females) previously reported, i.e., complete inhibition of growth, some mortality, and a rickets-like condition which was accompanied by a bony plate formation near the head of the tibia. Return to a stock diet with no beryllium sulfate brought about healing of the rickets but the bony plate remained. Pathological studies disclosed injury to kidney, liver, gonads and bone by 5% BeSO₄, rachitic-like bone injury to all rats and liver injury to some rats by 5% beryllium carbonate. Some bone deposition of beryllium was demonstrated by spectrochemical analysis. In the diet of rats, 10% beryllium sulfate caused 100% mortality in 10 days. When fed to dogs, 1 gm/kg/day of beryllium sulfate and 5 gm/kg/day of beryllium oxides had no effect on growth and produced no pathological changes.

'Curare-like' action of synthetic quaternary derivatives of stilbene. BERNARD P. MCNAMARA and TERESA SILVERMAN (by invitation), Medical Div., Army Chemical Center, and Univ. of Maryland, School of Pharmacy, Baltimore, Md. Four synthetic quaternary derivatives of stilbene have been investigated for their effects on neuro-

muscular transmission. The compounds are 1) Stilbestryl bis (2-(4-morpholino-ethyl) ether, bis methiodide, 2) Stilbestryl bis (2-diethylamino-ethyl) ether, bis methiodide, 3) Stilbestryl bis (3-diethylaminopropyl) ether, bis methiodide, 4) Stilbestryl bis (3-(2-methyl-piperidino) propyl) ether, methiodide. All four compounds exert a 'curare-like' action in rabbits and frogs. The paralyzing dose in rabbits is 0.1 mg/kg or less for these ethers. Several differences between their actions and those of curare (Intocostin) have been observed. Following intravenous administration of the stilbene derivatives in rabbits there is a delay of 5-15 minutes in the onset of paralysis. Neither prostigmine nor physostigmine antagonizes the paralysis produced in rabbits by these compounds.

Acute and subacute toxicity of 1,2,3 trichloropropane in mice and rabbits. Wm. A. McOMIE and T. R. BARNES (introduced by Hamilton H. Anderson), Div. of Pharmacology and Experimental Therapeutics, Univ. of California Medical School, San Francisco, Calif. The approximate time required for 1,2,3 trichloropropane to kill (within 48 hours) 8 of 15 mice exposed to a vapor concentration of 30 mg/l, was 20 minutes (at 22°C). Subsequently, liver damage accounted for 4 additional deaths, 7-10 days later. Immediate depression of respiration was noted, believed due to activity on the respiratory center. Subacute exposures over 10 days for 10 minutes each, at 15 mg/l, resulted in 7 deaths among 10 mice. In rabbits, 1,2,3 trichloropropane was an intense skin irritant, due in part to its solvent action on lipoidal components. Sloughing and cracking followed development of irritation and erythema. Ten applications of 2 ml each over 100 sq cm during 15 days resulted in subdermal bleeding and a painful reaction. One of 7 animals died after repeated exposure. Congested lungs were apparent. The remaining rabbits survived and healed with return of hair growth within 6 weeks. Our findings with 1,2,3 trichloropropane confirmed previous reports on the toxicity of chlorinated hydrocarbons. Since 10-minute repeated exposures to saturated vapor-air mixtures caused delayed deaths in mice, prolonged observation after contact is indicated. Inhalation should be avoided, as well as skin exposure, since systemic pathologic changes may follow. Romensky (1872) provided experimental observations on response to 1,2,3 trichloropropane. Paralysis was observed in frogs. Sleep and lowering of body temperature were noted in rabbits. In man, 3 gm orally caused sleepiness, marked headache, unsteady gait, and pain in the lumbar regions. Meyer (1899) reported paralysis of the respiratory center and serious effects on the heart.

A new antiadrenergic agent, 2-[N-p'-tolyl-N-(m'-hydroxyphenyl)-aminomethyl]-imidazo-

line HCl (C-7337) ROLF MEIER (by invitation) and FREDERICK F YONKMAN *Research Depts of Ciba, Basle, Switzerland, and Summit, N J* This new antiadrenergic agent was developed by Marver and Miescher in the imidazoline series as reported by Meier (N Y Acad of Sciences Conference, 1947) It is adrenergic in small doses and sympatholytic in higher concentrations Its antiadrenergic properties have been demonstrated as follows: Protection of mice from lethal effects of epinephrine intravenously, reversals in version of epinephrine hypertension in several species, inhibition or nullification of sustained vasoconstriction by epinephrine perfusion in the rabbit, obliteration of epinephrine's contractile effect of the isolated uterus of the rabbit, inhibition of the contractile action of epinephrine on the seminal vesicle of the guinea pig, nullification of adrenergic salivation in the cat and inhibition of adrenergic retraction of the feline nictitating membrane The antisymphathetic activity of C-7337 seems to be greater than that of Priscol and Dibenamine Its general tolerability locally and systemically is of real potential advantage and in this sense resembles Priscol

Comparative effect of digitoxin and ouabain on auriculo-ventricular conduction in the dog heart RAFAEL MÉNDEZ and JOSE PISANTY (by invitation) *Dept of Physiology and Pharmacology, National Inst of Cardiology, Mexico, D F, Mexico* There has been considerable controversy as to whether differences, other than in speed of action or elimination, exist between the effects of different cardiac glycosides The action of digitoxin (Digitaline Nativelle) and ouabain (Arnaud) upon A-V conduction was studied in dogs with the heart exposed under chloralose anesthesia Electrodes were attached to the right auricle and the ventricles Measurements of A-V conduction were taken during stimulation of the auricle at a constant frequency The glycosides were injected at 30-minute intervals in doses calculated to kill the heart in about 3 hours The results are summarized in the table

Digitoxin vs Ouabain on A-V Conduction

% of Lethal Dose (% of time necessary to kill the heart)	A-V Conduction Rate in % of Normal	
	Digitoxin (9 experiments)	Ouabain (9 experiments)
10	98.1	100.8
20	95.3	101.0
30	89.8	99.9
40	81.0	95.9
50	64.5	87.9
60 (Block beyond this dose)	56.8	77.0

Within its therapeutic range (30-50% of LD) digitoxin causes a significantly more pronounced lengthening of the A-V interval than ouabain

This effect although apparently mediated by the vagi seems specific on conduction for no significant differences were found in the effects of the two glycosides upon the sinus rate or rhythm The effect is also independent of any action on the pacemaker as measurements were done under constant frequency stimulation

Potency and pharmacological actions of nerifolin, a glycoside of *Thevetia Nerifolia* KALMAN C MEZEY (introduced by M B Chenoweth), *Cesar Uribe-Piedrahita Research Labors, Bogota, Colombia* Nerifolin obtained from thevetia trees indigenous to Colombia has a cat unit of 0.20 ± 0.002 mg/kg The minimal emetic dose in pigeons is 0.050 mg/kg and in cats, 0.98 mg/kg The minimal systolic dose in *Hyla labialis* by the U S P XI frog method is 0.0035 mg/gm Nerifolin is partially absorbed from the gastro-intestinal tract and exerts unusually marked action on isolated intestine It is completely eliminated in about 72 hours Except for oral absorption nerifolin most closely resembles ouabain pharmacologically

Reaction of cholinesterase with diisopropyl fluorophosphate containing radioactive phosphorus HARRY O MICHEL (by invitation) and STEPHEN KROP *Biochemistry and Pharmacology Sections, Medical Div, Army Chemical Center, Md* The possibility of compound formation between cholinesterase and diisopropyl fluorophosphate (DFP) was investigated by reacting a cholinesterase preparation from the electric tissue of *Electrophorus electricus* with P^{32} labeled DFP The preparation had an enzymatic activity of 2.6 gm of acetylcholine hydrolyzed/hr/mg of protein, as determined in 0.015M acetylcholine, 0.0342M $MgCl_2$ and 0.025M $NaHCO_3$ at pH 7.4 and 38°C The radioactivity of the labeled DFP was 19 millicuries per gram The reaction between the enzyme and DFP was permitted to proceed for 4 to 24 hours The cholinesterase was then precipitated with 5% trichloroacetic acid (CCl_3COOH) Horse serum protein was added as a carrier The precipitate was washed with CCl_3COOH and ethanol and then suspended in 0.02N NaOH Aliquots were dried and counted directly Phosphorus derived from DFP was found bound to protein in amounts directly proportional to the degree of inhibition of cholinesterase The amount of phosphorus bound to the completely inhibited enzyme was equivalent to 0.100 μg of DFP/mg of cholinesterase When DFP was replaced by sodium diisopropyl phosphate containing P^{32} , no phosphorus was bound by the enzyme

Relative potencies of various cinchona alkaloids in patients with auricular fibrillation WALTER MODELL, SAMUEL J SHANE (by invitation), CONRADO DAYRIT (by invitation) and HARRY GOLD *Dept of Pharmacology, Cornell Univ Medical College, Cardiovascular Research Unit of the*

Beth Israel Hospital, and Cardiac Service of the Hospital for Joint Diseases, New York City Six alkaloids, quinine, natural quinidine, synthetic quinidine, dihydroquinidine, cinchonine and cinchonidine were compared in 18 patients with auricular fibrillation by means of their effect on the rate of the circus movement as revealed by the deflections in the electrocardiogram. After a control tracing a dose was given orally on an empty stomach, and tracings were taken at intervals of 2 hours to determine the maximum effect. This was repeated at intervals of several days with a series of doses from 0.1 to 2.0 gm. The percentage slowing was plotted against the log of the dose. The results of the 244 experiments show that natural quinidine (a mixture of quinidine and dihydroquinidine), synthetic quinidine, and dihydroquinidine are of equal potency, that quinine and cinchonidine are about one half as potent, and that cinchonine is the least active, about one third as potent. The discrepancy between these results and those stated in the literature may be explained by the fact that the latter were not based on dosage-response curves and the doses used were so large as to fall in the insensitive range of dosage-response.

A method for the estimation of chloroform in small quantities of blood. LUCIEN E. MORRIS and EVAN L. FREDERICKSON (introduced by O. Sidney Orth). *Depts. of Anesthesiology and Pharmacology, Univ. of Wisconsin Medical School, Madison, Wis.* An improved method is presented which utilizes ether extractions and the Fujiwara color reaction of alkaline pyridine for rapid, accurate, photoelectric determination of chloroform in 1 cc. quantities of blood. Estimations of chloroform in the blood of anesthetized dogs gave values of from 18 to 50 mg. %, which compares closely with values obtained by earlier workers using more laborious or less delicate methods. Values found during clinical anesthesia indicate a marked species variation. Estimations of chloroform in the blood of 50 patients during anesthesia for major surgical procedures with chloroform as the sole agent gave an average value of 10 mg. % during maintenance.

Effect of pentobarbital on response of the cardiovascular system of dogs to epinephrine, acetylcholine and tilting. JAMES L. MORRISON, HARRY A. WALKER and ARTHUR P. RICHARDSON. *Dept. of Pharmacology, Emory Univ. School of Medicine, Emory Univ., Ga.* It has long been recognized that anesthesia alters the response of the circulation to the administration of many drugs, however, a quantitative description of these changes is at present lacking. We have attempted to obtain this information for pentobarbital. Unanesthetized dogs were tied to a tilting operating table and prepared for recording of blood pressure and intravenous injection of drugs. The response

of the circulation to the injection of a standard dose of epinephrine and acetylcholine in the unanesthetized state was determined. In addition, the response of the circulation to a sudden change in position was determined by tilting the animal from a horizontal to vertical position. Following these procedures, graded doses of pentobarbital were administered and the response to the standard test procedures redetermined after each dose of anesthetic. The injections of pentobarbital were continued until death of the animal. In a series of 6 dogs, the average lethal dose was 55 mg./kg. Gradually increasing doses of pentobarbital produced the following results: a) In the resting state pentobarbital produced a gradual fall in blood pressure with a decrease in pulse pressure and a marked increase in pulse rate. b) There was an increase in sensitivity to epinephrine characterized by a progressively greater rise in blood pressure, accompanied by a decrease and finally abolition of reflex bradycardia. c) There was an increase in sensitivity to acetylcholine characterized by a more prolonged fall in blood pressure and accompanied by a progressive decrease and final loss of reflex tachycardia. d) Pentobarbital produced a moderate postural hypotension accompanied by a loss of reflex tachycardia on tilting. These results can best be explained as being due to a selective central depression of reflex control of the circulation.

Antihistaminic properties of the β -haloalkylamine (dibenamine) series of adrenergic blocking agents. MARK NICKERSON and FRANCES B. HARRIS (by invitation). *Dept. of Pharmacology, Univ. of Utah College of Medicine, Salt Lake City, Utah.* The antihistaminic activities of 75 congeners of Dibenamine were determined by testing their ability to prevent histamine-induced contraction of the guinea pig ileum. All drugs were also tested against methacholine on the same preparation, with a very few exceptions the antihistaminic properties were found to be independent of significant cholinergic blocking activity. Antihistaminic activity in this series is not parallel to adrenergic blocking activity, but no compounds devoid of adrenergic blocking activity are among the more active antihistaminics. The β -haloalkyl grouping is essential for high activity. Substitution of a β -dimethylaminoethyl radical which provides maximal activity in several series of antihistaminics leads to inactivation. Phenoxyethyl (particularly 2-substituted) and α -naphthylmethyl amines are the most active. Unsymmetrical N-phenoxy-ethyl-N-benzyl compounds are almost always more active than N-diphenoxy-ethyl or N-phenoxyethyl-N-ethyl congeners. Several compounds with activities more than 10 times that of Benadryl are included in the series. In contrast to Benadryl and Pyribenzamine which produce a readily reversible 'equilibrium' blockade, members of this series produce a very

persistent blockade similar to that observed in connection with their adrenergic blocking action. Development of this blockade appears to occur in two stages. During the first stage these agents exhibit a competitive equilibrium with histamine which is no longer present after completion of the blocking action. A competitive inhibition of the action of these agents by Benadryl indicates a common site of action.

Mechanism of the acute lethal action of epinephrine in rats. MARK NICKERSON, JOHN BERGHOUT (by invitation) and ROBERT N HAMMERSTROM (by invitation) *Dept of Pharmacology, Univ of Utah College of Medicine, Salt Lake City, Utah.* Protection against the lethal effect of epinephrine in rats and mice has recently been employed as a test for adrenergic blocking activity. However, lack of information regarding the mechanism of death allows no definite conclusions regarding the specificity of this test. Sprague-Dawley rats were injected intraperitoneally with lethal doses of epinephrine, and protection was then provided by various physical procedures. Pentobarbital and heparin, employed in some of the tests, were found not to alter significantly either mortality or 'epinephrine' content of heart muscle as determined colorimetrically. Artificial respiration provides complete protection against several multiples of the lethal dose of epinephrine, but does not alter the 'epinephrine' content of the myocardium, which may be several times as great as that of control animals dying from smaller doses. Systemic arterial pressure stabilization also provides marked protection. In none of the animals was significant pulmonary edema observed. It is concluded that the lethal effect of epinephrine in rats is directly related to the induced increase in systemic arterial pressure which in turn induces respiratory failure. The mechanism of the last step is not clear, but it is not the same as that involved in transient 'epinephrine apnea'. Dibenzamine protects against the lethal effects of epinephrine but does not prevent 'epinephrine apnea'. Epinephrine toxicity in rats appears to be unrelated to an accumulation of the agent (or related catechols) in the myocardium.

Timed intravenous infusion of metrazol or strychnine in anticonvulsant testing. MARSHALL J ORLOFF (by invitation), H L WILLIAMS (by invitation), and CARL C PFEIFFER *Dept of Pharmacology, Univ of Illinois College of Medicine, Chicago, Ill.* The timed intravenous infusion of metrazol (0.5%) and strychnine (0.01%) makes possible an accurate graded evaluation of anticonvulsant compounds. The solutions are injected at the rate of 0.05 cc every 10 seconds into the tail vein of the mouse. Three signs of reaction follow each other in sequence as the concentration of metrazol is increased in the blood. These have

been designated as the 'first twitch,' the 'pseudo-convulsion,' and the 'persistent convulsion'. 'Tri-dione', phenobarbital, 'Dilantin', 'Phenurone', and 'Myanesin' have been used as anticonvulsants to test the accuracy of the method and to compare it with the subcutaneous metrazol method in general use. The chief advantages of the method are 1) fewer animals are necessary in order to evaluate the anticonvulsant, 2) it is less time-consuming than the subcutaneous metrazol method, and 3) it exhibits a high degree of sensitivity.

Effects of excess carbon dioxide in clinical anesthetic atmospheres upon cardiac automaticity and liver function. O SIDNEY ORTH, RALPH M WATERS, LUCIEN E MORRIS (by invitation), J L SIMS (by invitation), and ROBERT T CAPPS (by invitation) *Depts of Pharmacology, Anesthesiology and Internal Medicine, Univ of Wisconsin Medical School, Madison, Wis.* In the administration of anesthetics clinically there frequently is an accumulation of carbon dioxide in the respired atmosphere and a resulting systemic hypercarbia occurs. To determine the effects which such a condition might produce on cardiac automaticity and hepatic function in the human subject, moderate accumulations of carbon dioxide were produced either by permitting definite re-breathing or by the continuous addition of small amounts of carbon dioxide to the anesthesia bag while chloroform or ether was used as the sole anesthetic agent. Electrocardiographic observations were made continuously with the use of a direct recording machine and tracings were taken whenever desired. Analysis of the respired atmosphere was made every 3-5 minutes to prove the continuous presence of oxygen at or usually above 30%, and to know the percentage of carbon dioxide in the mixture. Blood samples were obtained periodically for determinations of hemoglobin, oxygen and carbon dioxide content and carbon dioxide capacity. Five tests of liver function, which included icterus index, cephalin-cholesterol flocculation, prothrombin time, bromsulfalein retention, and thymol turbidity, were made before the operation, 24 hours postoperatively, and every second day thereafter for 4 times or until liver function tests returned to normal.

Influence of roentgen rays on potency of penicillin. MARCUS OSTRO (by invitation) and DAVID I MACHT *Depts of Pharmacology and Radiology, Sinai Hospital, Baltimore, Md.* Aqueous solutions both of crystalline penicillin (C S C) and amorphous penicillin were treated with x-rays in open glass beakers, and compared pharmacologically with control non-radiated solutions of the same preparations. The apparatus employed was a water-cooled therapy tube operated on 200 K V and 20 M A with a target distance of 50 cm. The rays

employed were passed through a filter of 1 mm aluminium and 2 mm copper in some experiments, and a filter of 1 mm aluminium and 0.5 mm copper in others, the dosage employed in each case being the same. Dosages ranging from 93r to 280r were given to the solutions. Three kinds of tests were used for pharmacological comparison: 1) Phytotoxic tests on root growth of lupinus seedlings in plant physiological solutions revealed a greater phytotoxicity after irradiation through the 2 mm Cu filter, ranging from 20 to 30%. 2) The thromboplastic properties of penicillin after irradiation were also markedly increased, often 50% or more. 3) Bacteriological tests were made through the cooperation of Drs. Lawrence and Jerome Martin of the CSC Research Laboratories. These revealed no difference in chemotherapeutic and bacteriostatic potencies between γ -rayed and control solutions. The difference in the phytotoxic and thromboplastic properties occurred only when solutions of penicillin were irradiated, but did not occur when solid penicillin was exposed to γ -rays. Irradiations of mice with above filtered γ -rays in doses from 63r to 93r did not render the animals more vulnerable to subsequent injections of large doses of normal penicillin.

Experimental safety of sorbitan monostearate and its polyoxyethylene derivatives SIDNEY G. PAGE, JR. (introduced by HARVEY B. HAAG) *Medical College of Virginia, Richmond, Va.* Three products were submitted for investigation, containing Sorbitan Monostearate (Span 60) and Polyoxyethylene Sorbitan Monostearates (Tween 60 and Tween 61). Weighed contents were suspended in chocolate syrup and administered 3 times daily for 28 days to a group of 60 subjects. These ranged in age from 20 to 49 and were physicians, technicians or junior medical students. Physical examinations, blood and urine studies were made before administration and after 14 and 28 days of continuous administration. Further examinations were made 14 days after discontinuing administration of these products. The clinical observations included body weight, blood pressure and pulse measurements, the urinalyses included color, reaction, specific gravity, sugar and albumin, in addition to a microscopic examination. The blood examinations included determinations of hemoglobin, erythrocytes, leukocytes and differential examination, chemical determinations were made of the plasma protein, NPN, sugar, calcium and cholesterol. No significant variations were observed in any of the physical, microscopic or other examinations during this entire study. These substances did not produce any untoward effects in this investigation.

Effects of inhalation of high concentrations of carbon dioxide THOMAS M. PARRY (by invitation), JOSEPH N. SPENCER (by invitation), WILLIAM

B. DRAPER, RICHARD W. WHITEHEAD and ROBERT L. ARENDS (by invitation) *Dept. of Physiology and Pharmacology, Univ. of Colorado Medical Center, Denver, Colo.* Observations on dogs in diffusion respiration indicate that there is a progressive rise in blood carbon dioxide and a concomitant fall in blood pH during respiratory arrest. To determine the effect of the concentrations of CO₂ upon the blood pH, dogs were administered 10, 20, 30 and 40 % of carbon dioxide in oxygen for a period of 45 minutes while under light thiopental anesthesia. Changes in heart rate, ECG, and blood pH were noted, as well as the respiratory, anesthetic and toxic effects of the carbon dioxide mixtures. The inhalation of the carbon dioxide mixtures produced no significant change in the heart rate. Likewise, the only alteration in the ECG was an increase in the amplitude of the T wave, which returned to normal with the return of the blood to normal. The venous blood pH fell rapidly during the first 15 minutes of carbon dioxide inhalation, but thereafter decreased only slightly. The pH fell from a control average of 7.42 to 7.24, 7.05, 6.83 and 6.79 during inhalation of 10, 20, 30 and 40% carbon dioxide, respectively. Upon removal of the animals from the carbon dioxide atmosphere the pH rose rapidly. With 30 and 40% carbon dioxide the pH rose to 7.28 within 30 minutes while with 10 and 20% carbon dioxide it had returned to normal.

Effects of pituitrin, pitressin and pitocin on blood pressure and cardiac automaticity as modified by various anesthetic agents CARLOS E. PARSLÖE (by invitation), LUCIEN E. MORRIS (by invitation) and O. SIDNEY ORTH *Depts. of Anesthesiology and Pharmacology, Univ. of Wisconsin Medical School, Madison, Wis.* Accidents which have occurred following the administration of pituitary preparations to anesthetized patients make it desirable to reevaluate the pharmacological action and therapeutic uses of these drugs and to study any possible incompatibility which they may have with various anesthetic agents. Eighty-five experiments were made with 26 dogs. Anesthetic agents employed were either cyclopropane, ether, chloroform, nembutal, chlorotone or procaine. Unanesthetized animals also were studied. Blood pressure determinations and continuous electrocardiographic records were made and upon analysis subsequent to intravenous injection of each of the pituitary fractions the results were found to confirm and extend previous observations. Blood pressure response showed marked variation dependent on the type of anesthetic used. Most striking was a characteristic, almost precipitous fall in pressure observed after either pituitrin or pitressin during cyclopropane anesthesia. There were no significant changes following the use of pitocin. Alterations of cardiac rhythm were ob-

served in each of 14 conscious animals and in 9 with spinal analgesia. One-fifth of the animals tested with pituitrin or pitressin during cyclopropane anesthesia exhibited some type of arrhythmiae which was thought to be correlated with injection of the drug and associated with coronary constriction and a resultant myocardial hypoxia predisposing to cardiac dysfunction in the presence of anesthesia. Side effects of pituitrin administration, such as modification of respiratory activity to reduce effective exchange or retching and vomiting which may mechanically obstruct respiration, lead to increased hypoxia and are additional factors increasing the hazard of accident. Clinical electrocardiographic studies are in progress.

Antiseptic properties of certain mercurial diuretics. S. ANDERSON PEOPLES and ANN MCCORMICK (by invitation) *Division of Veterinary Science, Univ. of California, Davis, Calif.* Mercurial diuretics are rapidly excreted in the urine after intravenous administration, and if the compounds should then break down to give a sufficient concentration of ionized mercury, they would act as urinary antiseptics. In order to test this possibility, the *in vitro* antibacterial action of Salyrgan (I), Mercuzanthin, (II) Mercuhydrin (III) and mercuric chloride were tested against *Streptococcus faecalis*, *Streptococcus pyogenes*, *Escherichia coli*, *Staphylococcus aureus*, and *Corynebacterium renalis*. The concentration of mercury furnished by the compound in micrograms/cc required to inhibit growth was determined turbidometrically and the bactericidal concentration by subculture in thioglycollate media. The apparent percentage of the mercury in the compound which is ionized can be calculated from the ratio of the mercury as mercuric chloride to that of the compound required to produce the same endpoint. II was the most active, inhibiting all the organisms at 3-12, indicating that 50% of the mercury was ionized. I and III caused inhibition at 6-200, indicating 3-24% ionization. The bactericidal concentrations were difficult to determine accurately and varied from 12-400. These results were not materially altered when blood serum was added to the media nor when urine of pH 6.7 was used as media. The activity of all the compounds was increased by changing the pH of the media to either 5.0 or 8.0. These bacteriostatic and bactericidal concentrations can easily be reached in the intact animal and tests of these compounds in experimental urinary infections are now underway.

Release of various proteins from incubated surviving liver slices. RITA L. PESSOTTI (by invitation) and RALPH W. BRAUER *Dept. of Pharmacology and Experimental Therapeutics, School of Medicine, Louisiana State Univ., New Orleans, La.* In an effort to elucidate the factors which control the distribution of various plasma proteins

between the hepatic cells and the blood plasma, liver slices from dogs and rats have been incubated in protein-free or protein-containing solutions under various conditions. Analytical procedures applied include total protein determinations, esterase activity determinations, cholinesterase activity determinations, and electrophoretic analysis at pH 7.8. Results indicate that the release of protein with respect to the quantity, quality, and time course does not differ markedly as between different lobes of a liver obtained from the same animal, on the other hand, wide differences are obtained in going from one animal to the next. On incubation with Krebs solution at pH 7.4, the release of cholinesterase activity and of 'alpha globulins' proceeds much more rapidly than that of total protein. The addition of bovine plasma albumin to the incubation solutions accelerates and increases the amount of cholinesterase activity and of 'alpha globulins' released. These results parallel observations previously made in intact dogs under conditions of plasmapheresis or albumin transfusions. If liver slices are repeatedly transferred to fresh samples of Krebs solution a reduction in the rate of release of protein and of enzyme activity is usually observed after 2 or 3 transfers under the conditions of these experiments.

Nephrotoxic action of a cyanine dye, 1'-ethyl-3,6-dimethyl-2-phenyl-4-pyrimido-2-cyanine chloride. LAWRENCE PETERS and AEME HIGASHI (by invitation) *Dept. of Pharmacology, School of Medicine, Western Reserve Univ., Cleveland, Ohio.* Distribution studies in dogs following I.V. administration of dye showed its concentration in the kidneys to be higher than that in other organs. However, recovery from the urine never exceeded 10% of the dose given. Microscopic examination of unstained frozen-dried sections revealed the presence of large amounts of dye in the cells of the convoluted tubules. Doses greater than 10 mg/kg had a pronounced effect on renal function. Transient albuminuria occurred. Nitrogen retention, reflected in markedly elevated BUN and plasma creatinine concentrations, usually reached a peak between 48 and 96 hours, returning to normal over a variable period, depending on magnitude of dosage and individual susceptibility. Renal clearance values for inulin, creatinine, PAH (low and high plasma levels), glucose and sulfamerazine were all depressed during azotemia. The clearance of PAH (CP_{PAH}) at low plasma levels (0.8-1.8 mg %) fell less than the inulin clearance, hence the filtration fraction (CI/CP_{PAH}) was decreased. During recovery the clearances returned to levels equal to or only slightly in excess of pre-injection values. CP_{PAH} was again exceptional in that it increased 200-300%, resulting in a filtration fraction $\frac{1}{2}$ to $\frac{3}{4}$ of that existing before dye infection.

Though the dye possessed vasodepressor properties, the effects were obtainable following dye infusion at rates producing little or no fall in femoral arterial pressure. The animals were killed for post-mortem examination. Microscopically, sections revealed nephrotic changes confined principally to the cytoplasm of the tubule cells. Nuclear changes existed in some cases to be discussed.

Actions of 2,6-diaminopurine in mice, rats, and dogs **FREDERICK S. PHILIPS and J. B. THIERSCH** (by invitation) *Division of Experimental Chemotherapy, Sloan-Kettering Institute for Cancer Research, New York City*. Recent reports finding 2,6-diaminopurine, 1) an antagonist of folic acid and purine metabolism in microorganisms (Hitchings, et al *J Biol Chem* 174: 765, 1948), 2) a precursor in the synthesis of guanine in rats (Bendich and Brown, *J Biol Chem* 176: 1471, 1948), and 3) therapeutically active against leukemia in mice (Burchenal, et al *Cancer*, in press) led to studies of its pharmacology. Its toxicity by parenteral administration was determined in mice, rats, and dogs. Acutely toxic doses were fatal within 48 hours and in dogs caused protracted emesis, hemorrhagic diarrhea, severe losses of fluid and electrolyte, hemoconcentration, and collapse. However, daily doses as great as $\frac{1}{2}$ to $\frac{1}{3}$ LD-50 were tolerated by rats and dogs for 1 to 2 weeks or longer. Signs of chronic intoxication included anorexia, progressive weight-loss, and in peripheral blood, reticulocytopenia, leucopenia, and moderate anemia. Bone marrow from rats sacrificed in terminal stages of chronic intoxication was semi-fluid exhibiting significant depletion of both myeloid and erythroid elements. In dogs receiving daily doses serial bone-marrow aspiration revealed progressive diminution of total nucleated cell counts involving greater decreases in erythroid than in myeloid cells. Terminally nucleated erythroid cells were almost absent while myeloid cells in all stages were present, but, in less than normal quantities. In its effects on marrow and intestinal epithelium 2,6-diaminopurine resembled 4-amino-pteroylglutamic acid with regard to site of action. However, the actions of the purine and the folic acid antagonist could be differentiated in so far as the former failed to elicit megaloblastic erythropoiesis in dogs while the latter appeared to be more uniformly toxic to both myelopoiesis and erythropoiesis.

Quantitative estimation of pyribenzamine in blood **ALBERT J. PLUMMER** (introduced by **GEORGE I. MAISON**) *Dept of Pharmacology, Boston Univ School of Medicine, Boston, Mass.* With the cooperation of the Ciba Pharmaceutical Company, a chemical method for the quantitative estimation of pyribenzamine in blood has been developed. While this method is not as sensitive as the fluorimetric method of R. Mizzoni it is simpler. The

method 20 ml of blood are added to 30 ml of 15% Trichloroacetic Acid. The precipitated protein is removed by filtration and the filtrate, about 35 ml, is rendered just alkaline with 10% sodium hydroxide. The filtrate is extracted with two 15 ml portions of ether and these are combined and evaporated to dryness over a warm water bath. The residue is dissolved in 0.5 ml of 0.1% sulfuric acid and 1 ml of water. After allowing 5 minutes for solution the liquid is transferred to a Klett colorimeter tube and diluted to 5 ml. Iodine solution, 0.25 N, 0.04 ml is added and after 10 minutes the turbidity is read in colorimeter using No. 50 filter. The amount of pyribenzamine may be estimated by comparison with the readings obtained by developing turbidity in solutions of pyribenzamine hydrochloride of known concentration. It has been possible to measure with an error of plus or minus 5% amounts as low as 0.05 mg pyribenzamine hydrochloride added to 100 cc of human blood. The method is also applicable to the determination of antistine in blood. Here however, at present, the lowest detected concentration has been 0.3 mg per 100 ml of blood. No property of normal blood has interfered with the application of the method.

Augmentor effect as postulated by the electromotive theory of drug action **HARRY J. PRATT** (by invitation) and **R. BEUTNER** *Hahnemann Medical College, Philadelphia, Pa.* According to the electromotive theory of drug action, the stimulating action of a drug is proportioned to the electromotive change which it brings about at a phase boundary of water and an 'oil'. If the stimulant drug is an alkaloid like pilocarpine, the electromotive effect on the phase boundary is a negative variation, like the negative variation brought about by stimulation of nerve. This electric effect of the drug is enhanced by addition of sodiumbenzoate or other sodium of organic acids, but only within certain limits, a larger or smaller addition of benzoate will decrease the electric effect, (Beutner, *J Pharm* 34: 29, 1928). The stimulating action of pilocarpine, as tested on the isolated intestine of rabbit, is likewise enhanced by addition of sodiumbenzoate, this also occurs only within certain limits of concentration as experiments show, but only two single measurements by Storm van Leeuwen and von György were available so far to test the theory. In order to obtain additional data, the following experiments were made. To a strip of rabbit duodenum, suspended in Tyrode solution, 0.03 mg of pilocarpine was added. They produced a contraction of 45 mm. This was reduced 43% by 0.03 mg of sodiumbenzoate, it was potentiated 30% by 0.165 mg, 71% by 0.33 mg, 20% by 1.65 mg, 33% by 3.3 mg, and again reduced 28% by 16.5 mg or 70% by 33 mg. These data show that the potentiation of the constricting action of pilo-

carpine occurs only within certain limits as does the electric effect

Inhibition of myocardial reactions to epinephrine and nor-epinephrine by nitroglycerine W RAAB and EUGENE LEPESCHKIN (introduced by F J SICHEL) *Division of Experimental Medicine, Univ of Vermont, College of Medicine, Burlington, Vt* In atropinized cats the blood pressure and electrocardiogram were recorded after intravenous injection of epinephrine and nor-epinephrine (probably identical with sympathin) and after faradic stimulation of the stellate ganglia. The injections were followed by elevation of the blood pressure, tachycardia and transient flattening or inversion of the T-wave in leads CR1 and CR4 (between the 15th and 50th seconds) and later (until about the 160th second) usually by elevation of T. The effects of epinephrine and nor-epinephrine were almost identical, and similar to those produced by stimulation of the stellate ganglia. If nitroglycerine was injected together with epinephrine or nor-epinephrine, the effect of the latter on blood pressure and tachycardia was weakened, the depression of the T-wave was either entirely abolished or markedly diminished. This effect was considerably greater than would correspond to the slight or moderate elevation of T, sometimes elicited by nitroglycerine alone. Since the depression of T had proven entirely independent of blood pressure and heart rate, the inhibiting effect of nitroglycerine is assumed to take place in the myocardium itself through interference with the metabolic action of the sympathomimetic amines. As epinephrine is believed to dilate the coronaries, it seems unlikely that the inhibition of the epinephrine-induced electrocardiographic changes through nitroglycerine should be due to a further coronary dilatation. The T-wave depression after stimulation of the cardiac sympathetic was likewise inhibited by nitroglycerine. It is probably due to discharges of nor-epinephrine into the myocardial cells.

Purification of the toxic principle of agene-treated gluten for pharmacological study JACK L RADOMSKI, GEOFFREY WOODARD, and HENRY N FUYAT (introduced by ARNOLD J LEHMAN) *Division of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D C* To facilitate the study of the pharmacology of canine hysteria it was desirable to purify the responsible etiological agent. The starting material was prepared by the hydrolysis of agene (NCl_3)-treated gluten with pancreatin. The pH of a batch of toxic hydrolysate was depressed stepwise to progressively lower values by the addition of a cationic exchange resin (Ion X) in its H^+ form. The resin was filtered off each time a desired pH was reached. This process was repeated until the pH was depressed beyond the range of interest.

Thus, the peptides and amino acids of this hydrolysate were fractionated according to the pH range in which they become adsorbable. Each of the batches of resin was separately eluted with dilute ammonia and the toxicity of the eluate determined by oral administration to dogs. It was found that the toxic principle was adsorbed exclusively between pH 3.35 and pH 3.95. It is felt that this method is generally applicable for the separation of peptides from protein hydrolysates and constitutes an improvement on previously published techniques. Further concentration was effected by washing the resin with dilute hydrochloric acid before the toxic principle was eluted with ammonia. The eluate may be dried to a white water-soluble powder with an acute toxicity of 500 mg/kg to dogs. This represents a 10-fold purification over the starting material. Still further purification was achieved by extraction with organic solvents. The pharmacological behavior of the partially purified toxic principle in dogs, monkeys, rabbits, and rats was investigated.

Metabolic factors contributing to the course of pentothal anesthesia CLAUDIA M RATLIFF (by invitation), A H MALONEY, JAMES R TUREMAN (by invitation) and WALTER M BOOKER *Dept of Pharmacology, School of Medicine, Howard Univ Washington, D C* Previous work reported from this laboratory has called attention to hyperglycemia and glycogenolysis under prolonged pentothal anesthesia. An extension of that work pointed out the indication for insulin during pentothal anesthesia. In the present work experiments are reported in which specific units of insulin are administered at regular intervals (intramuscularly) or by constant drip (intravenously) sufficient to keep the blood sugar in normal range during three hours of pentothal anesthesia. It has been found that insulin-treated animals require greater quantities and more frequent administration of pentothal sodium to keep them in surgical anesthesia as compared with untreated controls. Insulin treated animals have slightly higher liver glycogen values than untreated animals at the end of 3 hours of anesthesia. There is some evidence that the glycogen storage at the liver influences the destruction of pentothal, since in animals on high carbohydrate and on high protein diets, where the liver glycogen is high, accumulation of pentothal at the liver from hour to hour is less than in animals on normal diets. Taking liver samples every hour for pentothal and micro glycogen determinations, it has been found that the more rapidly the glycogen falls, the greater is the build up of pentothal at the liver. Furthermore, in animals on normal diet the liver is efficient the first hour in destroying pentothal, but as anesthesia is pushed into the second and third hours more and more pentothal can be demonstrated at the liver.

Induction of idioventricular rhythms by 1-1-trichlorethane and epinephrine BARBARA R. RENICK (by invitation), S. DONALD MALTON (by invitation), G. K. MOE and M. H. SEEVERS *Dept of Pharmacology, Univ of Michigan, Ann Arbor, Mich* Methyl chloroform was recommended as an anesthetic agent 60 years ago, but has never had clinical trial. In this laboratory attempts to induce anesthesia in 2 dogs without premedication led to sudden death, presumably cardiac in origin, in both animals. In 5 dogs under barbital anesthesia epinephrine was injected after administration of repeated small doses of methyl chloroform. Ventricular extrasystoles and ventricular tachycardia were produced in all animals. Maximum sensitization of the heart to epinephrine occurred after the administration of 0.25 to 0.4 cc/kg of methyl chloroform. Further administration of the agent raised the threshold dose of epinephrine, in part because of the resultant severe hypotension. Ventricular arrhythmias can be more regularly induced with methyl chloroform than with chloroform, but the sensitivity of the heart appears to be less than with cyclopropane.

Competitive inhibition of convulsions in guinea pigs R. K. RICHARDS and K. E. KUETER (by invitation) *Dept of Pharmacology, Abbott Research Laboratories, North Chicago, Ill* The authors have shown that para aminobenzoic acid (PABA) and diethylaminoethanol (DEAE), the split products of procaine, can either singly or, more efficiently, as a mixture inhibit the convulsions caused by 1 m injection of procaine in guinea pigs when administered i p prior to this drug. This work has been extended by using the dibutylamino-propyl (DBAP) ester butyn, a more potent local anesthetic of the PABA series. 30 mg/kg of butyn sulfate 1 m caused convulsions in 90% of the guinea pigs. This incidence could be reduced to about $\frac{1}{3}$ by pretreatment with 400 to 600 mg/kg PABA. DBAP and similar long-chain amino alcohols were too toxic for testing their possible antagonistic effect against butyn as it was demonstrated with DEAE in the case of procaine. Metycaine was studied because it is an ester of benzoic acid rather than of PABA. 45 mg/kg of metycaine HCl was convulsive in 82% of the animals. The incidence of convulsions was reduced to about 55% by premedication with comparable doses of either benzoic acid or PABA. As with butyn the metycaine side chain, 2-methylpiperidinopropyl, was relatively too toxic to investigate its possible antagonistic effect. These findings will be discussed from the viewpoint of the theory of competitive inhibition on the basis of structural similarity and the changes in pharmacologic properties which occur if the tertiary amino group of the amino alcohol is converted into a quaternary

ammonium base which deprives the esters of the local anesthetic properties.

Action of caffeine and aminophylline as respiratory stimulants in man GLENN H. RICHMOND (introduced by C. L. GEMMILL) *Dept of Pharmacology, Univ of Virginia, Medical School, Charlottesville, Va* The respiratory stimulating effect of CO₂ was used as a functional test to study the mechanism of action of caffeine and aminophylline as respiratory stimulants. Ventilation minute volumes were obtained with the subject breathing atmospheric air, 3% CO₂ in O₂, and 5% CO₂ in O₂ before and after the administration of 0.25 gm of caffeine subcutaneously and before and after the administration of 0.25 gm of aminophylline subcutaneously. The average increase in ventilation minute volume, of 6 subjects, when breathing 3% CO₂ was found to be 23% greater after caffeine than before. When breathing 5% CO₂ the increase was 51.7% greater after caffeine than before. It was concluded from this study that caffeine acts on the respiratory center by increasing its sensitivity to CO₂. Aminophylline was found to have no significant effect on the response of respiration to CO₂.

Lethal and electrocardiographic changes produced by quinine dihydrochloride in monkeys infected with *P. knowlesi* R. H. RIGDON (introduced by CHAUNCEY D. LEAKE) *Laby of Experimental Pathology and Heart Station, Univ of Texas, Medical Branch, Galveston, Texas* During our studies on malaria, quinine dihydrochloride was given to 31 monkeys. Some of those with a severe infection died immediately following an intravenous injection of quinine. Since other animals of equal weight survived a similar dose, experiments were designed to study this variation. To determine the effect of quinine on the electrocardiogram, 20 monkeys were used, 9 of which were normal and 11 infected with *P. knowlesi*. Limb leads and an apical chest lead were obtained and immediately thereafter quinine dihydrochloride was given intravenously and a second group of tracings was made during an interval of 10 minutes. A series of tracings were made on 4 monkeys given quinine both before and after their infection. In some experiments the dosage of quinine was varied to study its effect, while in other experiments the dose was kept constant to determine the variations accompanying the changes in the degree of parasitemia and the anemia. The lethal doses of quinine were 56 and 77 mg/kg for two normal monkeys. In contrast, the following doses, 28, 28, 28, 31, 37.5 and 47 mg/kg, were lethal for malarial infected monkeys who had red blood cell counts between 1.9 and 3.24 million. Malarial infection, per se, although severe, did not appear to affect the electrocardiogram in the majority of cases. In 3 monkeys the deleterious conduction and other electrocardiographic effects of quinine

were found to be greater when infected than when normal. In malarial infected monkeys the electrocardiographic changes following quinine appeared to parallel the degree of anemia rather than the degree of parasitemia.

Renal clearance of iodide in the dog DOUGLAS SHEPARD RIGGS *Dept of Pharmacology, Harvard Medical School, Boston, Mass*. Simultaneous clearances of iodide, chloride and creatinine have been determined in dogs maintained on a low-chloride, high-protein diet. The average glomerular filtration rate measured by the creatinine clearance was about 100 cc/minute. When plasma iodide concentrations were 1.6 mEq/l or less, the clearance of iodide was remarkably low, ranging from 0.05 to 0.79 cc/minute. With higher plasma iodide levels the clearance increased to as much as 8 cc/minute at 11 mEq/l of plasma. When plasma iodide was maintained at about 0.4 mEq/l and chloride excretion was elevated by the oral administration of sodium chloride, the clearance of iodide increased markedly to as much as 17.7 cc/minute. The iodide clearance was always somewhat greater than the chloride clearance, the difference being most marked when the chloride excretion was moderate. When chloride excretion was very high, the kidney seemed less able to differentiate between the two halides. This dependence of iodide excretion on chloride excretion resulted in prolonged retention of iodide in dogs whose kidneys were conserving salt. For example, a plasma iodide level of 1.2 mEq/l was maintained without appreciable change for 24 hours after a single subcutaneous injection of sodium iodide in a fasting animal. Administration of sodium chloride occasioned a prompt and profound fall in plasma iodide. These experiments indicate that the tubular reabsorption of iodide in the dog may be almost complete when total halide excretion is minimal.

Effects of 3-acetoxy phenoxy trimethylammonium methylsulphate on neuromuscular function WALTER F. RIEKER and W. CLARKE WESCOE (by invitation) *Dept of Pharmacology, Cornell Univ Medical College, New York City*. In the gastrocnemius-soleus preparation of the intact cat the close intra-arterial injection of 3-acetoxy phenoxy trimethylammonium methylsulphate (Nu 2017, Hoffmann-LaRoche, Inc.) produces an immediate maximal contraction of the muscles followed by intense local fasciculations. The fasciculations disappear completely within one minute. If the dose is sufficiently large, the fasciculations become generalized. The close intra-arterial injection of 5 μ g/kg potentiates the response of the muscles supra-maximal nerve stimuli. The duration of the potentiation is brief in contrast to that produced by physostigmine, neostigmine, and DFP. Varying degrees of depression of the muscular response to supra-maximal nerve stimuli are produced by large

doses of Nu 2017. The recovery from depression is rapid and the return to normal from a completely refractory state occurs within 20 minutes. After inactivation of cholinesterase by DFP, the close intra-arterial injection of a large dose of Nu 2017 produces a profound depression from which recovery is prolonged. The depression of the response to indirect stimuli produced by d-tubocurarine is antagonized by Nu 2017.

Preparation and pharmacological properties of the acid succinate of myanesin RICHARD F. RILEY and F. M. BERGER (introduced by HAROLD C. HODGE) *Depts of Pharmacology and Pediatrics, Univ of Rochester, Rochester, N. Y.* Observations on the metabolic fate of myanesin led to the assumption that myanesin acid succinate would represent a soluble, relatively non-toxic derivative of myanesin with a less intense and longer duration of action. In the present investigation, the succinate was prepared and tested and found to behave in accordance with this expectation. The succinate, prepared by reacting myanesin with succinic anhydride in pyridine, was obtained as straw-colored, extremely viscous liquid which gives a highly water soluble sodium salt. In the mouse, the paralytic and lethal doses of sodium myanesin succinate are found to be larger than those of myanesin. The antagonism and duration of action of these two drugs to metrazole convulsions was studied by the injection of these compounds before and after the administration of an LD₉₉ of metrazole. On a molar basis, the succinate is less effective in preventing convulsions when administered jointly with metrazole. The succinate is, however, equally effective when administered prior to the convulsant. The succinate in small doses abolishes tremors and hyperexcitability due to strychnine without abolishing the knee jerk in the cat.

Failure of alpha tocopherol to influence chest pain in patients with heart disease SEYMOUR H. RINZLER (by invitation), HYMAN BAKST (by invitation), ZACHARY H. BENJAMIN (by invitation), AUDRIE L. BOBB (by invitation), and JANET TRAVELL *Cardiovascular Research Unit of Beth Israel Hospital and the Dept of Pharmacology, Cornell Univ Medical College, New York City*. A stringent blind-test method, in which neither patients nor examiners knew whether alpha tocopherol or a matching placebo was being administered, was used to investigate effects of alpha tocopherol on long standing chest pain in 38 ambulatory clinic patients with heart disease (chiefly arteriosclerotic and hypertensive). For allotment to control and treated groups, patients were paired with respect to sex, age, cardiovascular status, duration and type of chest pain, and other pertinent factors. One of each pair was assigned to either control (placebo) or treated (vitamin) groups. Types

of chest pain encountered were effort angina, constant chest pain, and intermittent chest pain unlike effort angina. We regard the first group as primarily of cardiac origin, while the other two are considered chiefly somatic. The dosage plan was 200 mg of synthetic alpha tocopherol (Ephynal Acetate 'Roche') by mouth daily for 2 weeks and thereafter 300 mg daily. The average duration of vitamin administration was 16 weeks (10-20 weeks), and of the placebo 16.6 weeks (10-20 weeks). Response to medication was similar for both groups. No improvement was noted in 12 treated subjects (63%) and 14 controls (73%). Subjective improvement was reported by 7 treated patients (37%) and 5 controls (27%). Serial electrocardiograms, exercise tolerance tests, repeated blood pressure readings and measurements of skeletal muscle function did not reveal significant differences between treated and control groups. Our results fail to confirm the reported benefits of alpha tocopherol in cardiac pain.

Pharmacologic and sensitizing properties of SY-28 when administered by ion transfer. ARTHUR A RODRIGUEZ (by invitation), JULES H. LAST, and ADOLPH ROSTENBERG JR (by invitation). *Depts of Physical Medicine, Pharmacology, Dermatology and Allergy Unit, Univ of Illinois College of Medicine, Chicago, Ill.* The pharmacologic activity of SY-28 (N-ethyl-N-(1-naphthylmethyl)- β -bromoethylamine hydrobromide) was studied following administration by ion transfer to the normal skin of human subjects. Three-tenths of a milliamperere of anodal current was applied to 10 cm² areas of the skin. A total amount of 0.3 cc of a 10 mg % solution of SY-28 in propylene glycol was used. It was observed that SY-28 when administered in the above manner was a strong eczematous sensitizer. Twelve out of 46 patients (26%) became sensitized to the drug. Adrenergic blocking activity, lasting at least 24 hours, was demonstrated in 53 patients. Antihistaminic activity was also noted following administration of SY-28. There was clearly no interference with the pharmacologic action of SY-28 in those individuals who became sensitized.

Interaction between hematin and serum albumin. MORRIS ROSENFELD and DOUGLAS M. SURCION (by invitation). *Dept of Pharmacology and Experimental Therapeutics, Johns Hopkins School of Medicine and Dept of Physical Chemistry, Harvard Medical School Boston, Mass.* The reaction between hematin and human serum albumin to form methemalbumin has been studied by spectrophotometric procedures. Titration of hematin with albumin reveals a one to one molar ratio at the endpoint. Other interactions involving simple stoichiometric relationships are indicated by titration curves. Little interaction is observed spectrophotometrically with other plasma protein frac-

tions including fibrinogen and the alpha, beta and gamma globulins. A direct colorimetric procedure for the estimation of serum albumin has been based on the hematin reaction. The colorimetric measurements compare favorably with values obtained by the low temperature methanol fractionation method of Pillemer and Hutchinson.

Thiomerin toxicity and diuretic effects. A. RUSKIN, J. E. JOHNSON, W. N. RODDY (introduced by CHAUNCEY D. LEAKE). *Heart Station, Univ of Texas Medical Branch, Galveston.* The disodium salt of N-(γ -carboxymethylmercaptomercuri-B-methoxy) propyl camphoramic acid (thiomerin) in isolated rabbit hearts causes A-V and I-V block and asystole in doses 20 times those of meralluride (mercuhydrin), and about 50 times those of mersalyl-theophylline and mercuzanthin. In 50 clinical cases the diuretic effects of 2 cc doses of thiomerin subcutaneously are approximately equivalent to those of 2 cc doses of mercuhydrin intravenously, both containing the same amount of mercury (80 mg) in organic combination. Cases in which mercuhydrin produced untoward effects (nausea, vomiting, muscle cramps, toxic psychoses), tolerated thiomerin well. Rare local soreness and nodulation from thiomerin is now being investigated by similar comparative methods.

Adrenergic blocking agents and the vasopressor response to epinephrine. DAVID RUSSELL (by invitation) and GRAHAM CHEN. *Research Labs, Parke, Davis & Company, Detroit, Mich.* Quantitative results on 'epinephrine reversal' of blood pressure in the dog have been obtained with two adrenergic blocking agents: N-(2-bromoethyl)-N-ethyl-1-naphthalenemethylamine HBr and yohimbine. The data were found to conform to either Langmuir's adsorption isotherm or Gaddum's equation of competitive inhibition based on the law of mass action. A linear relationship is obtained when the degree of 'epinephrine reversal' is expressed in terms of the percentage of inhibition of epinephrine in probit units and the doses of the adrenergic blocking agent in logarithms.

Action of cholinesterase inhibitors on the isolated rabbit ileum. P. R. SALERNO (by invitation) and J. M. COON. *Dept of Pharmacology, Univ of Chicago, Chicago, Ill.* It has been reported by us (*Fed Proc* 7:212, 1948) that physostigmine, neostigmine, TEPP, and DFP, in molar concentrations of approximately 10⁻⁵, change the pendular movements of the isolated rabbit ileum to a peristaltic rhythm. The appearance of moving constriction rings in the muscle strip characterizes this change. The peristaltic rhythm can be reversed to a pendular rhythm by atropine and thiamine, or by the ganglionic blocking agents procaine, nicotine, tetraethyl ammonium and magnesium. Effective concentrations of the latter

blocking agents have no effect upon the sensitivity of the gut to acetyl choline added to the bath. The change in rhythm cannot be induced in the untreated muscle by acetylcholine itself. Gut preparations kept at 1°C for 2 days exhibit a typical pendular activity when placed in oxygenated Ringer-Locke at 37.5°C and respond to the esterase inhibitors by an increase in tone but not by the usual change in rhythm. After four days the gut is totally insensitive to the cholinesterase inhibitors and nicotine but responds to acetylcholine, pilocarpine, barium, and epinephrine. The cholinesterase activity of rabbit ileum was found to be stable at 1°C for at least 25 days. It is believed that the conversion from pendular to peristaltic rhythm induced by the cholinesterase inhibitors in the isolated gut depends upon the endogenous synthesis of acetylcholine and the integrity of the intrinsic ganglion cells. The loss of sensitivity in the old intestinal strips might be caused by a degeneration of the ganglion cells and a cessation of acetylcholine synthesis.

Inotropic synergism between digitalis bodies and serum calcium WILLIAM T. SALTER, JOHN GEMMEL (by invitation) and LOUIS SCIARINI (by invitation) *Dept of Pharmacology, Yale Univ School of Medicine, New Haven, Conn.* The hypocalcemic frog heart can be employed with a few ml of human serum or Locke's solution to test the inotropic potency of a cardiac glycoside. By adjustment of the concentration of Ca^{++} ions, graded stages of hypodynamic contraction can be produced serially. Such preparations at pH 7.3 follow the law $R/(100 - R) = [\text{Ca}^{++}] - (A - k[G])$, where R is the percentile contractile response of the heart, $[\text{Ca}^{++}]$ the concentration of calcium ions, A the individual 'heart constant', k the potency of the cardiac glycoside and [G] its concentration. Each preparation is calibrated in standard mammalian Ringer's solution to determine the 'heart constant' A. Then the $[\text{Ca}^{++}]$ is adjusted and the response R measured when the test heart has been equilibrated with the dissolved preparation or serum under test. Finally the value $k[G]$ is calculated. When $R = 50\%$, $k[G] = A - [\text{Ca}^{++}]$. In terms of ouabain, it is difficult to avoid toxic effects at concentrations higher than 5 micrograms %, even when the $[\text{Ca}^{++}]$ is low.

Isopropyl alcohol as an anticonvulsant RALPH W. SCHAFFARZICK (by invitation) and P. J. HANZLIK *Dept of Pharmacology and Therapeutics, Stanford Univ School of Medicine, San Francisco 15, Calif.* The minimum effective blood acetone for anticonvulsant action (cortical threshold by electrical stimulation) in rats receiving acetone gastrically was found to be about 50 mg % which could be nearly doubled and the threshold raised 100% with excessive doses, without ataxia. The minimum effective anticonvulsant blood concen-

tration of alcohol, after isopropyl alcohol gastrically in rats, was markedly irregular. After 500 mg and 1250 mg/kg doses of isopropyl alcohol gastrically, the increase in cortical threshold paralleled more closely the blood alcohol than the blood acetone. When the higher dose of the alcohol was given in 3 divided doses in 12 hours, the acetone was cumulative with peak increases in cortical threshold in 1 hour, recovery at end of 12 hours, and suggestions of tachyphylaxis to the cortical stimulus (rats and rabbits). Generally the acetone outlasted the anticonvulsant action (6-hour observations). Only about 3% (average) of the higher dose of the alcohol was excreted in 24 hours in the urine of rabbits, the ratio of excreted alcohol to acetone being about 2.3 to 1. The share of alcoholemia and acetone in the anticonvulsant action of isopropyl alcohol remains undetermined. Surely convulsant but generally not fatal doses of metrazol (50-70 mg/kg) and picrotoxin (2-3 mg/kg) subcutaneously were partially antagonized by the higher dose of isopropyl alcohol gastrically in the great majority of rats.

Effect of some vasodilators and sedatives on gastric secretion ROBERT B. SCHLESINGER (by invitation), F. STEIGMANN and LEO L. HARDT (by invitation) *Hektoen Inst for Medical Research of Cook County Hospital and the Dept of Therapeutics of Cook County Hospital and the Depts of Internal Medicine, Univ of Illinois, College of Medicine and Stritch School of Medicine, Loyola Univ, Chicago, Ill.* Because some patients have epigastric discomfort after the ingestion of some vasodilator and sedative drugs, the effect of such substances on gastric secretion was studied on 32 patients (21 with duodenal ulcer and 11 controls). The gastric contents were aspirated every 15 minutes and returned to the stomach except 10 cc which were used for titration for gastric acidity. Following the fourth aspiration one of the drugs to be tested was administered. The following drugs were tested, 1) aminophylline, gr VI enteric coated, 2) aminophylline, gr III plain, 3) sodium nitrite, gr I, 4) glucophylline, 4.68 gr, 5) nicotinic acid, 100 mg, 6) butisol tablets, gr ISS (sodium 5-ethyl-5-sec-butyl barbiturate), 7) elixir of butisol fl oz 1 (gr III) given orally, 8) aminophylline, gr 72 and 9) glucophylline 36 gm administered intravenously. Aminophylline and glucophylline intravenously and tablets and elixir of butisol increased the free acid, the total HCl and the volume. Nicotinic acid and aminophylline tablets (gr VI) increased the volume and total HCl. Glucophylline, aminophylline (gr III), and sodium nitrite decreased the free acid, the volume and the total HCl in all but 3 patients. Since aminophylline and glucophylline orally did not increase acidity, increased free acid following intravenous aminophylline (average 21 units) and

glucophylline (average 10 units) may result from central stimulation. The epigastric distress in some individuals is probably due to other causes than increased gastric acidity, although results of single gastric analyses must be cautiously interpreted.

Fluorimetric vs biologic assays (human and animal) of fractions of digitalis purpurea. LOUIS SCIARINI (by invitation) and WILLIAM T. SALTER, *Dept of Pharmacology, Yale Univ School of Medicine, New Haven, Conn.* Tincture of digitalis has been fractionated into 5 arbitrary extracts, based largely on differential solubility in chloroform and rather concentrated solutions of sulfuric acid. To each of these a fluorimetric procedure has been applied and the value compared with Harry Gold's human oral assay and/or with well-substantiated assays by the intravenous cat or pigeon methods. The relative significance of each fluorimetric value, measured against crystalline digitoxin as a standard, is given by the conversion factor F , when $F \times$ the fluorimetric value = biological activity. Even so, a correction must be made for digitoxin. The oral human activity resides almost exclusively in fraction V. The data suggest that the oral potency of digitalis purpurea is due solely to its digitoxin content. For our fraction V, a series of Harry Gold's preparations (in terms of digitoxin per gram of powdered leaf) gave: A) by Gold's human assay, a) 1.14, b) 1.15, c) 1.08, d) 1.43 and e) 1.02, respectively; B) by fluorimetry a) 1.14, b) 88.6, c) 1.09, d) 1.43 and e) 1.07, respectively. Much of the biological activity after intravenous injection of lethal doses into cats or pigeons occurs in fractions II and III. For example, in one preparation the percentile lethal activity (pigeons) in various fractions was: I) 36%, II) 21%, III) 14%, IV) 7% and V) 21%. For such values, a series of conversion factors (based on intravenous, animal, lethal effects) can be determined.

Distribution and excretion of beryllium sulphate using Be^{10} as a tracer. JAMES K. SCOTT and WILLIAM NEUMAN (introduced by H. C. HODGE), *Dept of Radiation Biology, Univ of Rochester, Rochester, N. Y.* Beryllium sulphate was administered intravenously to rats and rabbits; the rate of blood clearance, the urinary and fecal excretion and the distribution to organs was determined by counting techniques. In some cases nonradioactive beryllium sulphate was added to the isotopic beryllium sulphate. More than 95% of the beryllium was cleared from rabbits' blood during the first 5 hours after administration; the rate of clearance was more rapid when isotope alone was administered than when carrier was added. The urinary excretion of beryllium was greatest during the first 6 hours after administration; thereafter small amounts less than 1% were excreted daily. In rabbits and rats a higher % of the isotope was

excreted when isotope alone was given than when carrier was added: 28% and 11%, and 35% and 25% respectively. The total fecal excretion over a 7-day period was approximately 10% of the dose in the rats and 2% in the rabbits. When carrier was administered with the isotope approximately 35% was found in the skeleton of the rat and 51% in the skeleton of the rabbit; when isotope alone was administered the skeletal recovery was 48% and 54%. The amount of isotope recovered from the liver and spleen of the rat was insignificant when isotope alone was administered and amounted to 12% and 2.5% respectively when carrier was added. Significant amounts of beryllium were present in the bone marrow when carrier was administered with the isotope. The kidneys contained less than 1% of the dose.

Tachyphylaxis of sympathomimetic drugs. LLOYD D. SEAGER and WILLIAM WEISS (by invitation), *Depts of Pharmacology and Anesthesiology, Woman's Medical College of Pennsylvania, Philadelphia, Penna.* A comparison was made of a number of sympathomimetic drugs as to their property of showing tachyphylaxis. Blood pressure response in vagotomized dogs and cats was the function studied. Of the drugs studied, the phenomenon was found to occur most readily with desoxyephedrine. In some experiments, complete tachyphylaxis with reversal was found following an initial dose of 1 mg/kg. Oenethyl, propadrine, benzedrine, ephedrine and paredrine were next in order of susceptibility. As tachyphylaxis developed to any of these agents, the animal was found to show diminished or no response to the others of the group. A reversal of blood pressure after repeated dosage occurred most readily with desoxyephedrine and oenethyl but could be produced with large doses of the other compounds. Reversal was usually associated with some slowing of the pulse. Some diminution of the response to neosynephrine, and epinephrine was found after massive doses of ephedrine, desoxyephedrine, benzedrine, oenethyl, and propadrine. Nicotine was usually found to give some increase in blood pressure after complete tachyphylaxis had developed to one of the sympathomimetic agents.

Epinephrine and dibenamine in the alarm reaction. JOSEPH SEIFTER, WILLIAM E. EHRLICH, ALBERT J. BEGANY (by invitation), and GEORGE M. HUDYMA (by invitation), *Wyeth Inst of Applied Biochemistry, and the Graduate School of Medicine of the Univ of Pennsylvania, Philadelphia, Penna.* Colchicine is considered the most potent stimulus available for provoking the alarm reaction, characterized by involution of lymphoid tissue and shock. Since discharge of epinephrine is thought to be the first consequence of exposure to an alarming stimulus, it was of interest to determine whether the administration of epinephrine en-

hances the toxicity of colchicine and whether the administration of an adrenolytic drug decreases the toxicity of colchicine. Results, 1) epinephrine is a less intense alarming stimulus than colchicine, 2) dibenamine (dibenzyl- β -chloroethylamine HCl) produced a mild alarm reaction, which subsided in 24 hours, 3) non-lethal doses of epinephrine combined with non-lethal doses of colchicine resulted in fatality, with extreme alarm reaction, 4) dibenamine protected against the lethal effects of either colchicine or epinephrine, but not against the combination of colchicine and epinephrine, 5) the histological changes of the alarm reaction in the thymus and the adrenals provoked by epinephrine were reversed by dibenamine, but those provoked by colchicine were not.

Effects of certain central nervous system depressants and stimulants on intermediary metabolism of brain. F. E. SHIDEMAN, *Dept. of Pharmacology, Univ. of Michigan, Ann Arbor, Mich.* The results presented here are preliminary data obtained from experiments designed to determine differences in biochemical behavior of 'stimulants' (convulsants) and 'depressants' (anesthetics) as judged by their *in vitro* actions on isolated central nervous system tissue. The effects of a series of central depressants and stimulants on no-substrate oxygen consumption of rat cerebral mince were determined. In no case was there obtained any significant effect other than inhibition. Excellent correlation between relative *in vitro* and *in vivo* potency was obtained in the depressant series of drugs but was not apparent in the stimulant series. A representative member of each group (chloral hydrate and metrazol) was employed for further studies in concentrations which had produced equal inhibitions of the Q_{O_2} of rat cerebral mince. The degree of inhibition of the no-substrate Q_{O_2} of brain mince with both compounds paralleled a) the degree of specialization of the tissue and b) the phylogenetic development of the animal species studied. With glucose, lactate, pyruvate, α -ketoglutarate and fumarate, Δ -substrate oxygen consumptions of rat cerebral cortex mince were equally well inhibited by both chloral hydrate and metrazol. When succinate was added as a substrate the 2 drugs showed a quantitative difference in their effects. Both compounds had the same qualitative effect on anaerobic glycolysis of rat cerebral mince but differed quantitatively. Whereas metrazol increased anaerobic glycolysis 25%, chloral hydrate effected a 100% increase in the $Q_G^{N_2}$.

Production of ventricular extrasystoles in the dog by a polypropylene glycol. F. E. SHIDEMAN and G. K. MOE, *Dept. of Pharmacology, Univ. of Michigan, Ann Arbor, Mich.* A polypropylene glycol with an average molecular weight of 750 produced ventricular extrasystoles when it was administered intravenously in the anesthetized

dog. The total amount required to produce the extrasystoles varied (10 mg/kg to 90 mg/kg) from animal to animal but the duration appeared to depend on the total amount of polyglycol administered rather than on the size of a single dose. In no experiment was it possible to produce ventricular fibrillation either by further administration of polyglycol or by epinephrine, once extrasystoles had been established. Bilateral vagotomy in no way influenced the extrasystoles. Epinephrine or tetraethylammonium chloride in some cases caused transient disappearance of the cardiac irregularity, but not in others. Administered in divided doses in the heart-lung preparation, the polyglycol produced increasing degrees of decompensation and finally complete failure. In this preparation, and in artificially respired animals with the heart exposed, extrasystoles were never produced by the polyglycol alone or combined with peripheral vagal or cardiac sympathetic stimulation. However, when in the open chest preparation, the respiratory volume was reduced to a point where the animal displayed respiratory efforts, extrasystoles were readily induced and could be abolished by increasing the respiratory volume. Such findings would suggest that the sensitivity of the heart to this polypropylene glycol is dependent in some way on a relative anoxia.

Distribution effect and fate of oil aerosol particles after retention in the lungs of mice. MILTON SHOSHKES, WILLIAM G. BANFIELD, JR., and S. JOSEPH ROSENBAUM (introduced by AMEDEO S. MARRAZZI), *Toxicology, Pathology, and Aerosol Sections, Medical Division, Army Chemical Center, Md.* Mice were exposed to mists of corn, peanut, cod liver, mineral, and motor oils, with an average mass median diameter of 2.5μ in dynamic chamber-type experiments. The general dispersion of the retained oil droplets in the lung was found to be equal from apex to base and from hilus to pleura, and the highest concentration was noted in and around the terminal bronchioles and alveolar ducts. In a statistical analysis of the distribution and size of corn oil particles retained in the lung, it was noted that 80% of all the particles retained in all areas of the lung were 2.5μ or less in diameter. The initial concentrations of retained oil droplets in the lung after exposure to all the oil mists were similar. However, during a 96-hour period of observation, the concentration of the edible oils decreased progressively, while the concentration of the paraffin oil droplets remained essentially unchanged. Except for the appearance of scattered macrophages, no acute inflammatory changes were seen after a 2-hour exposure to these oil mists within a 96-hour observation period. After heavy exposures, mineral and motor oil droplet retention resulted in localized foreign body reactions of moderate severity as well as infrequently occurring

patches of lipid pneumonia. Cod liver oil droplets caused a moderate foreign body reaction and only negligible reactions to corn and peanut oil were seen.

Effect of renal dysfunction on the urinary excretion of fluoride in the rabbit F A SMITH and D E GARDNER (introduced by H C HODGE) *Dept of Radiation Biology, Univ of Rochester, Rochester, N Y*. The effect of uranium-produced nephritis on the urinary excretion of ingested fluoride has been studied in rabbits receiving 1) a subcutaneous injection of 0.3 mg U/kg as uranyl nitrate, 2) the same dosage of uranium in addition to 15 ppm fluoride in the drinking water, and, 3) 15 ppm fluoride in the water supply. Control urinary fluoride excretion was determined. Inspection of the analytical data shows that within 3 to 4 days after injection of the nitrate, the urinary excretion of fluoride decreased to a level only $\frac{1}{2}$ as great as obtained prior to the uranium injection. Twelve days after the injection, the urinary fluoride level was again normal in those rabbits which were not receiving fluoride in the drinking water, only 4 days were required for the return to normal levels of urinary excretion in those animals whose water supply contained added fluoride. Fluoride content of the tooth and bone indicated that the presence of uranium in the kidney may inhibit the deposition of ingested fluoride in the bone and thus offer a degree of protection against fluorosis. The fluoride contents of the tooth root, femoral epiphysis and jaw alveolar bone for rabbits receiving only added fluoride were significantly higher than in comparable tissues from rabbits treated with both uranium and fluoride, despite the greater quantity of fluoride consumed by these animals. Other supporting evidence for the protective effect of added fluoride on uranium poisoning was 1) a 2.5-fold lower blood N and, 2) lowered mortality.

Rate of removal of alcohol in acutely intoxicated chronic alcoholics H W SMITH and R G BELL (introduced by J K W FERGUSON) *Dept of Pharmacology, Univ of Toronto and Shadowbrook Health Foundation, Toronto, Canada*. The rate of removal of alcohol from the blood of 21 chronic alcoholics prior to treatment with intravenous insulin (40 U zinc insulin), glucose (50 ml of 50%) and 'Betalin' (Lilly, 2 ml) was compared to the rate during treatment. This rate was increased during treatment by 9.9% ($S^2 = 3.3\%$) when the rate was calculated on the basis of % of the amount of alcohol present. Seven untreated patients showed no change in the hourly rate of removal of alcohol from the blood during comparable periods of study.

Effects of tetraethylammonium chloride on pain thresholds in man RALPH R SONNENSCHN (by invitation), ELIZABETH H JENNY (by invita-

tion) and CARL C PFEIFFER *Depts of Pharmacology and Clinical Science, Univ of Illinois College of Medicine, Chicago 12, Ill*. The intravenous injection of 500 mg of tetraethylammonium chloride (9 trials on 4 subjects) raised significantly the pain threshold of the finger pad, lowered that of the nail bed, and left practically unaffected that of the tooth. Thresholds of the nail bed and pad of the 3rd finger were determined by a radiant heat device. Tooth thresholds were determined by electrical stimulation of the pulp through a metal filling, both the perceptive threshold (TI) and affective threshold (TII) were measured. Over a 30-minute period following injection, pad threshold showed an average maximum rise of 14% ($P < 0.001$), at this point, 10 minutes after injection, the nail threshold was decreased by 6% ($P < 0.02$). No consistent, significant change was seen in tooth thresholds. Preliminary experiments (Pfeiffer et al *Ann N Y Acad Sci* 51: 21, 1948) reveal that procaine block of the stellate ganglion, with Horner's syndrome, causes a rise in nail and fall in pad threshold. It therefore is unlikely that the above action of TEA is due to ganglionic blockade. Block of the median nerve with 0.5% procaine causes a rise in pad and fall in nail threshold. The effect of TEA is another example of this reciprocal relationship. The evidence indicates that pain of nail bed and pad is mediated by 2 separate mechanisms. The primary action of TEA in raising pad threshold may be through a selective peripheral or central effect on the underlying mechanism for pain from this area.

Clinical criteria in beryllium poisoning C J SPIEGL, F A SMITH, L J LAFRANCE, J W KEATING (introduced by H C HODGE) *Dept of Radiation Biology, Univ of Rochester, Rochester, N Y*. At present no reliable biochemical methods exist for the diagnosis of early or mild forms of beryllium poisoning. Accordingly a broad survey of clinical criteria was made in animals undergoing exposure. This included urinary protein and amylase, blood nonprotein nitrogen, urea nitrogen, serum protein, serum albumin-globulin ratio, fibrinogen, serum calcium, phosphorus, acid and alkaline phosphatase, arterial oxygen tension, 10 lipid fractions of the blood with special attention to phospholipid and free cholesterol concentrations in the red cells. Dogs and rabbits were studied that had been exposed to beryllium sulfate at concentrations ranging from 1 to 100 mg/m³ and beryllium oxide at from 10-85 mg/m³ for periods up to 100 days. Of the many criteria applied, arterial oxygen tension and red cell concentrations of free cholesterol and phospholipid gave indication of potential value as clinical procedures in following the course of beryllium injury. Many of the other criteria failed at lower levels of injury.

Cocaine-barbiturate antagonism JOHN E

STEINHAUS (introduced by A L TATUM) *Dept of Pharmacology, Univ of Wisconsin Medical School, Madison, Wis* A quantitative study of cocaine-barbiturate antagonism was undertaken to evaluate the effectiveness of prophylactic doses of barbiturate for toxic reactions of local anesthetics A series of young, male, New Zealand, white rabbits (1.5 to 2.5 kg) were injected subcutaneously with doses of cocaine ranging from 100 to 300 mg/kg They were then treated intravenously with various doses of pentobarbital at different time intervals with respect to the cocaine injection It was found in these studies that higher doses of cocaine required correspondingly higher doses of pentobarbital With symptomatic treatment the average dose of pentobarbital required for rabbits receiving 300 mg/kg of cocaine was almost double that required for animals in the 100 mg/kg series The time of pentobarbital administration for maximal effectiveness was at the time of cocaine injection Treatment 45 minutes before or 15 minutes after this time was ineffective When 100 mg/kg (the generally accepted LD₅₀) of cocaine was given subcutaneously, 15 mg/kg of pentobarbital resulted in 100% survival, whereas 5 mg/kg gave no protection These data suggest that the protection afforded by barbiturate depends upon the degree of depression and that approximately $\frac{1}{2}$ of the anesthetic dose is required for adequate protection This would make it appear questionable that the commonly used 'prophylactic' dose (0.1 to 0.2 gm orally) gives adequate pharmacodynamic protection

Comparison of the acute toxicity of hydroquinone and some related di and trihydroxy benzenes JAMES H STERNER (by invitation), STANLEY AMES (by invitation) and DAVID W FASSETT *Eastman Kodak Company, Rochester, N Y* Recent developments in use of polyhydroxy benzenes as antioxidants in fats for human consumption have stimulated an interest in their relative toxicologic properties The acute oral and parenteral toxicity of hydroquinone (HQ), nordihydroguaiaretic acid (NDGA), n-propyl gallate (NPG) and butylated hydroxy anisole (BHA) reveals certain marked differences with respect to onset and character of symptoms, time of death, and a wide spread between the ratio of parenteral and oral LD₅₀ values In the white rat, the approximate LD₅₀ in mg/kg intraperitoneally were NDGA—70, HQ—168, BHA—250, NPG—250, orally, the values were HQ—370, NDGA—2400, NPG—2500, BHA—2500 The rapid onset of symptoms and the occurrence of death within 30 minutes with hydroquinone contrasted sharply with the delayed onset of symptoms and marked variability in time of death with the other antioxidants which varied from a few minutes to 7–10 days The apparent recovery of the hydroquinone survivors was very rapid, a matter

of an hour or two, compared with the prolonged inanition and debility of the survivors of the animals given NDGA, BHA, and NPG These results suggest a fundamental difference in excretion and metabolism of hydroquinone (a normal excretory product in urine) and the compounds of more complex structure

Pharmacologic action of chlordane E F STOHLMAN, W T S THORP and M I SMITH *Experimental Biology and Medicine Inst, National Insts of Health, Bethesda, Md* The acute toxicity, LD₅₀ of chlordane in rats was found to be approximately 250 mg/kg when given orally in olive oil or Tween 20 The LD₅₀ of DDT under similar conditions is 150 mg/kg On intraperitoneal injection chlordane in Tween 20 was slightly more toxic than when given in olive oil In rabbits the LD₅₀ of both compounds is approximately 300 mg/kg Death from chlordane poisoning may be delayed for many days Chronic toxicity of chlordane was considerably greater in both rats and rabbits than that of DDT under similar conditions, probably due to greater cumulative effects of chlordane Repeated administrations of chlordane orally produced in rabbits focal necrosis of the liver, degenerative changes in the proximal convoluted tubules of the kidneys, and pulmonary exudates in the alveoli and bronchioles of the lungs, whereas with large single doses the primary effect appeared to be on the lungs, producing focal hemorrhages Organically bound chlorine was excreted in the urine of rabbits to the extent of about 18% of the dose given, most of it during the first 4 days following administration Significant amounts of organic chlorine were excreted in the urine of rabbits following 25 mg/kg or more chlordane

Acute inhalation toxicity of beryllium sulfate in animals H E STOKINGER, G F SPRAGUE, R H HALL, J K SCOTT, F A SMITH, B H BROWN, and A PETTINGILL (introduced by H C HODGE) *Dept of Radiation Biology, Univ of Rochester, Rochester, N Y* The acute toxicity from inhalation of beryllium sulfate mist in animals was determined in large-scale experiments wherein the toxic limits of exposure and the characterization of the acute response were established A series of 4 concentrations (100, 50, 10 and 1 mg BeSO₄ 6H₂O/cu m of air) were tested in daily 6-hour exposures for periods of from 14–105 days Particle size of the mist was from 0.5 to 1.3 μ Marked species variation in response was noted At levels of 100 and 50 mg/m³, 80–100% mortality occurred during week 1–6 in the cat, dog, rat, goat and monkey, 60% (week 1–2) in the guinea pig, 10–50% (week 2–5) in the rabbit, mouse and hamster, all swine and fowl survived Over-all mortality, chiefly confined to the rat, at 10 mg/m³ was 14%, at 1 mg (0.04 mg Be/m³) no mortality was observed in any species and weight losses were recovered at the

end of 90 days' exposure although certain evidences of poisoning were still present. The monkey, dog, cat and rabbit showed acute pulmonary inflammatory response, resembling that in man, the rat gave an atypical response. Effects that were severe and rapid in onset at the 100 and 50 mg -levels were minimal and slower in developing at the 10 mg -level changing to moderate with continued exposure and, at the 1 mg-level, were nonexistent in certain species at the end of 105 days' exposure. Highest levels produced severe proteinuria and changes in blood protein values, not apparent at lower levels. At the lowest level, reduced blood oxygen tension and alteration in blood cell lipid ratios occurred. A hypochromic macrocytic anemia appeared in the dogs. Beryllium concentrations in 20 tissues were determined. A control study with NaHSO_4 must show that the lesions produced in BeSO_4 exposures were due to beryllium and not to the sulfate ion.

Protective effect of certain drugs on epinephrine-induced pulmonary edema. CLEMENT A. STONE (by invitation) and EARL R. LOEW, *Dept of Physiology, Boston Univ School of Medicine, Boston, Mass.* Studies were made with certain drugs to determine their ability to prevent the pulmonary edema in rabbits following an intravenous injection of 0.375 mg/kg of epinephrine as the base. Protective drugs were injected intravenously 10 minutes prior to the epinephrine. The indication of efficacy was the presence of a statistically significant reduction in lung weight and/or mortality from that of a series of concurrent control experiments. Previous reports (Luisada, *Arch f exper Path u Pharmacol*, 132: 313, 1928) indicate that hypnotics in general are effective in reducing mortality due to epinephrine. Pentobarbital sodium (25.0 mg/kg) in our experiments was ineffective in preventing the hemorrhage and edema of the lungs, which is the usual cause of death after large doses of epinephrine. Atropine sulfate (5.0 mg/kg) significantly diminished the increase of lung weight, but not mortality, as compared to controls, but was not as effective as N-(2-chloroethyl)-N-ethylbenzhydramine HCl (SY-2, 2.5 mg/kg) or N-(2-bromoethyl)-N-ethyl-1-naphthalenemethylamine HBr (SY-28, 0.25 mg/kg). These drugs are potent adrenergic blocking agents, SY-28 having, in addition, a marked ability to antagonize histamine. The complete protection afforded by SY-2 and SY-28 is probably related to their ability to annul the acute hypertensive action of epinephrine. The failure of Neoantergan (2.5 mg/kg), a potent and specific antihistaminic, to protect indicates that histamine does not play a prominent role in the edema formation. The protective effect of relatively large doses of the anti-histaminic, Phenergan or 3277 R.P. (*Acta allergologica*, 1: 97, 1948) may be related to other

properties, among which is an appreciable atropine-like action.

Hypotensive activity of fractions from green Hellebore. J. W. STUTZMAN, GEORGE L. MAISON and G. W. KUSSEROW (by invitation), *Dept of Pharmacology, Boston Univ School of Medicine, Boston, Mass.* and *Product Development Dept., Rezell Drug Company, Los Angeles, Calif.* Fifty fractions of green hellebore were tested for hypotensive activity in normotensive dogs which were unanesthetized or lightly anesthetized with pentobarbital sodium. On intravenous administration the fractions were found to fall into three groups on the basis of hypotensive action. One group did not alter mean arterial pressure, a second caused a gradual minimal fall, and a third an abrupt fall with slow recovery over several hours. The last group included both water soluble and organic solvent fractions. In this group hypotension was accompanied by bradycardia of short duration. Minimal effective intravenous dosage was 0.002 mg/kg from a fraction which represented 0.35% of the crude drug. Potent fractions were effective orally at a dosage of 0.2 mg/kg. Toxic effects of high doses included retching, emesis, apnea, hypertension and convulsions.

Comparative anticonvulsant potencies of some phenylhydantoins and their corresponding phenylacetylureas. EWART A. SWINYARD and JAMES E. P. TOMAN, *Depts of Pharmacy, Pharmacology and Physiology, Univ of Utah College of Medicine and College of Pharmacy, Salt Lake City, Utah.* Anticonvulsant potencies (ED_{50}) of 5-phenyl-5-R-hydantoins (h) and their corresponding phenyl-R-acetylureas (a) were determined by their ability to modify maximal electroshock seizure pattern and to prevent Metrazol convulsions in rats. Drugs were given orally in 10% neutral acacia suspension and tested at the previously determined time of peak drug effect. Minimal neurological toxicity (TD_{50}) was determined, and protective indices ($\text{P.I.} = \text{TD}_{50}/\text{ED}_{50}$) were calculated. Maximum potency occurred with alkyl substitutions. Unsubstituted phenylacetylurea (Phenurone) was superior to its hydantoin homolog, whereas diphenylacetylurea was inactive in contrast to diphenylhydantoin (Dilantin). Studies on the metabolic fate of these compounds might help to identify a common denominator as the effective product.

Purification of diamine oxidase (histaminase). HERBERT TABOR, *Experimental Biology and Medicine Inst., National Insts of Health, Bethesda, Md.* A highly purified, stable diamine oxidase has been obtained from an extract of hog kidney acetone powder with the aid of a new colorimetric procedure for the estimation of histamine (Rosenthal and Tabor, *J Pharm Exp Therap*, 92: 425, 1948). The acetone powder was extracted with

0.2M phosphate buffer pH 7.2, and fractionated with Na₂SO₄ (14.5-21%). This fraction was dialyzed, heated to 60°C for 20 minutes, adsorbed on alumina gel C₇, and eluted with 0.1M K₂HPO₄. The dialyzed eluate was fractionated with ethanol at 0°C, and dried *in vacuo*. This dry preparation is 500 times more active per mg protein than the original extract, and represents a yield of approximately 25% 0.006 mg of this purified powder destroys 0.03 mm of histamine in 5 minutes in an incubation mixture containing 0.1 mm of histamine and 1.3 mg of crystalline bovine albumin (as a protective protein) in 3 cc of 0.1 M phosphate buffer pH 7.2 (37°C). Further purification can be obtained by adsorption on calcium phosphate gel and elution with phosphate buffer. The action of diamine oxidase on histamine probably results in destruction of the imidazol ring, since the products give no color with diazotized p-nitro aniline. In the destruction of putrescine and cadaverine, neither succinic acid nor γ -amino valeric acid, respectively, could be detected. The mechanism of breakdown of these diamine compounds is being further investigated.

Comparative study of the local toxic action of thiomerin, mercuzanthin and mercurhydrin. HARRY TAUBE (by invitation), Robert A. LEHMAN and E. E. KING (by invitation) *Dept of Therapeutics, New York Univ College of Medicine, New York City*. The mercurial diuretic thiomerin, (di-sodium salt of N-[gamma-carboxymethyl-mercaptomercuri, beta-methoxy] propylcamphoramic acid), has been compared with mercuzanthin and mercurhydrin with respect to the gross pathology produced following subcutaneous injection in the abdomen of the mouse and the histopathology occurring after intramuscular injection in the Tibialis anterior muscle of the rat. It was found that thiomerin was tolerated by the mice without gross pathologic changes while the other 2 drugs gave rise to varying degrees of necrosis under the same conditions. Intramuscular injection in the rat was selected for the histologic studies because of the greater homogeneity of the tissue and accuracy in the administration of the drugs. Results were put on a semi-quantitative basis by scoring each muscle according to the type and extent of response. Serial sections were prepared in every instance and were examined throughout by the same pathologist without foreknowledge of the treatments given. All 3 drugs were found to elicit an early inflammatory response characterized by the appearance of a polymorphonuclear infiltrate. In the case of thiomerin this exudate was entirely resorbed within 96 hours without evidence of residual damage. Ninety-six hours after injection of mercuzanthin or mercurhydrin there was evidence of marked fibroblastic proliferation indicating the irreversible character of the initial reaction to these drugs.

The relationship of chemical constitution to local toxicity will be discussed.

Comparison of local anesthetic activity of certain aliphatic amines. HERBERT W. TAYLOR, JR (by invitation), EDWIN J. FELLOWS, EDWARD MACKO (by invitation) and GLENN E. ULLYOT (by invitation) *Research Division, Smith, Kline and French Labs, and Dept of Pharmacology, Temple Univ School of Medicine, Philadelphia, Penna*. The comparative local anesthetic activity and irritant properties of 32 volatile aliphatic amines have been determined in rabbits by topical application of solutions of the free bases and neutral salts.

Both anesthesia and irritation decreased as the molecular weight was decreased in homologous series and as the point of attachment of the nitrogen was moved toward the center of the carbon chain. The effect of alkylation of the nitrogen or of the carbon chain was irregular. Among these compounds 2-methylaminodecane and 2-amino-2-methyloctane were found to be very active anesthetic agents in concentrations which did not produce irritation.

Effect of tridione (3,3,5-trimethyl oxazolidine-2,4-dione) on the respiration of mouse brain. J. D. TAYLOR (by invitation), R. K. RICHARDS, and G. M. EVERETT (by invitation) *Dept of Pharmacology, Abbott Research Labs, North Chicago, Ill*. The effect of Tridione on the O₂ uptake of mouse cerebral cortex slices in Krebs-Ringer phosphate solutions containing different substrates was determined by means of the Warburg technique. With glucose, pyruvate, lactate, succinate, acetate, citrate and glutamate as substrates, only glucose showed a significant inhibition with 3.5×10^{-2} M Tridione. At 7×10^{-2} M concentration of Tridione, oxygen consumption was inhibited in all substrates. Inhibition in glucose was the greatest (32%) and acetate the least (17%). In 1.4×10^{-1} M Tridione, inhibition ranged from 62 to 76% depending on the substrate, except for succinate and citrate where inhibition was 33 and 54% respectively. The depression of oxygen uptake by 7×10^{-2} M Tridione in glucose was removed by washing the brain slices after 30 minutes exposure to the drug. The addition of p-phenylenediamine to the inhibited respiring brain slices partially restored the oxygen uptake but glutathione, adenosine triphosphate and creatine were ineffective. Tridione in concentrations up to 7×10^{-2} M did not inhibit anaerobic CO₂ production of mouse brain brei in Krebs Ringer-bicarbonate. With 1.4×10^{-1} M Tridione there was 26% inhibition. Statistically significant inhibition of O₂ uptake in glucose was also observed in brain slices taken from mice 30 minutes after intraperitoneal injection of 1 or 2 gm/kg of Tridione. Calculations show that the amounts of Tridione used in these Warburg studies are within the pharmacological range of those used *in vivo*.

Determination of diethylstilbestrol in urine

R S TEAGUE, CHRISTIAN WINGARD (by invitation), and ALBERT E BROWN (by invitation) *Dept of Pharmacology, Medical College of Alabama, Birmingham, Ala* A method for the extraction and determination of free and conjugated diethylstilbestrol in urine using the Dingemans antimony pentachloride reaction has been developed. The method consists of the following steps. Urine is acidified and extracted with ether. Free and conjugated diethylstilbestrol are separated by partitioning between ether and aqueous sodium bicarbonate. The free material is then purified by washing the ether solution with aqueous sodium carbonate, extraction with normal sodium hydroxide, neutralization to pH 11 with phosphoric acid, and extraction with ether. The ether is evaporated and the residue taken up in ethanol. Aliquots of the ethanol solution are evaporated, the residues dissolved in absolute anhydrous chloroform, antimony pentachloride is added and the density of the resulting color estimated photoelectrically. The bicarbonate solution containing conjugated diethylstilbestrol is acidified with phosphoric acid and extracted with ether. The ether is removed, the residue taken up in decinormal sodium hydroxide, and brought to pH 2.8 with phosphoric acid. Hydrolysis is accomplished by autoclaving aliquots of this solution at 180° for 30 minutes. The solutions are then extracted with ether and purified as for free diethylstilbestrol. Recoveries of diethylstilbestrol added to urine have been near 100% and of added diethylstilbestrol glucuronide 90%. In the case of a patient to whom a dose of 100 mg of crystalline diethylstilbestrol was given orally, the urinary excretion in four days was found to be 8.0 mg of free diethylstilbestrol, 6.1 mg conjugated, a total of 14.1 mg.

An attempt to systematize the actions of epinephrine substitutes on smooth muscle organs
C H THIENES, JACK LANLEY (by invitation) and WAITER MATTISON (by invitation) *School of Medicine, Univ of Southern California, Los Angeles, Calif* A series of compounds chemically related to epinephrine have been tested on isolated small intestine, colon, and uterus of dog, cat, rabbit, rat, and guinea pig and their actions compared with the effect of epinephrine. No consistent relations could be demonstrated, except with arterenol, cobefrine, epinine, metasynephrine, metahydroxy-propadrine, and parahydroxy-propadrine, all of which had actions quite similar to epinephrine on all tissues. The remainder of the compounds were inconsistent in that on some types of organ, or organs of a given animal, the actions were similar to those of epinephrine, on others dissimilar, some compounds were even inconsistent to the extent of

causing contraction of an organ at one time and relaxation at another.

Thiocyanate excretion JESSELENE THOMAS (introduced by MARK NICKERSON) *Dept of Pharmacology, Univ of Utah College of Medicine, Salt Lake City, Utah* The use of thiocyanate in hypertensive patients is frequently accompanied by toxic reactions which persist for some time after the drug is discontinued. However, little is known concerning the mechanism of, or methods of promoting, thiocyanate excretion. The fact that thiocyanate and halogen distribution in the body are essentially the same suggested that renal thiocyanate excretion might be related to chloride in the same manner as bromide. Sodium thiocyanate calculated to give extracellular fluid levels of 15 mg % was injected intravenously into dogs under pentobarbital anesthesia. Diuresis was established by means of water orally, or 5% glucose or 1.8% sodium chloride solution intravenously. Blood and urine samples were collected at intervals and analyzed for thiocyanate and chloride. Sixty thiocyanate clearances provided a range of values from 0.1 to 7.1 cc/minute. Chloride excretion ranged from 0.003 to 1.42 mEq/minute and urine flow from 0.8 to 9.9 cc/minute. Thiocyanate clearances were plotted against chloride excretion for each animal, and a straight-line relationship was obtained in every experiment. Partial coefficients of correlation were found to be +0.92 (P < 0.02) for the relationship of thiocyanate clearance to chloride excretion, and only +0.33 for the relationship of thiocyanate clearance to urine flow. It is concluded that renal excretion of thiocyanate is essentially the same as that of chloride. Thiocyanate excretion may be greatly increased by the administration of NaCl.

Cytological effects of alloxan in intact and thymectomized rats

THURLO B THOMAS (by invitation), PAUL L EWING and G A EMERSON *Dept of Zoological Sciences, Carleton College, Northfield, Minn, and Dept of Pharmacology, Univ of Texas Medical Branch, Galveston, Texas* Thymectomy has been shown to increase the susceptibility of rats to the diabetogenic effects of 0.188-0.25 mm/kg of alloxan given intravenously, neither thymectomized nor intact rats become hyperglycemic after 0.125 mm/kg (*Fed Proc*, 6:328, 1947). The cytology of the pancreas, liver, spleen, kidney, lung, adrenal, pituitary, lymph node, thymus and testis has been studied in the above thymectomized and intact rats. The principal cytological effect of alloxan in diabetogenic doses is marked and widespread reduction in nucleoprotein reserves. In thymectomized and intact rats fasted for 24 hr before and for 12 hr following alloxan injection, the cytological differences were slight, they involved a somewhat more severe loss of chromatin from the nuclei and ribonucleoprotein

from the cytoplasm of cells in the thymectomized animals. The cytological reaction in both of the above groups of rats was much more severe than in intact animals fasted for 40 hr before and only 4 hr after alloxan. Non-diabetogenic doses of alloxan had cytological effects in both intact and thymectomized rats differing only in degree from the above reactions. There appeared to be no direct correlation between the severity of alloxan diabetes, as measured by the blood sugar response, and the extent to which nucleoprotein reserves had been depleted.

Toxic effects of parenterally administered cetylpyridinium chloride. CHARLES R. THOMPSON (by invitation) and HAROLD W. WERNER, *Pharmacology Dept., Research Labs., Wm. S. Merrell Co., Cincinnati, Ohio*. Although quarternary ammonium salts are finding many types of applications clinically there are no data on possible toxic effects of repeated parenteral administrations to laboratory animals. Therefore, the effects of repeated parenteral administrations of one quarternary ammonium salt, cetylpyridinium chloride (Cepyrin Chloride) were investigated in rats and dogs. Daily subcutaneous and intraperitoneal administrations of cetylpyridinium chloride to rats for three weeks in doses of 2.5 mg/kg decreased the rate of growth. No gross or microscopic tissue alterations were observed which could be attributed to drug administration. The subcutaneous administration of cetylpyridinium chloride to dogs as a 2% aqueous pyrogen-free solution for 1 week in daily doses of 4 mg/kg caused local abscess formation, hematologic alterations, and toxic changes in the livers and kidneys. Dogs, in which perivascular damage followed the intravenous administration of 0.5% and 2% solutions in daily doses of 1 and 4 mg/kg for 3 weeks exhibited similar toxic changes. The intravenous perfusion of cetylpyridinium chloride in doses of 4 mg/kg as a non-irritating 0.1% solution caused no local tissue damage, hematologic alterations, or toxic liver and kidney changes. The systemic toxicity of parenterally administered cetylpyridinium chloride appears to be correlated with the local necrotizing action of the compound.

Comparison of the actions of chloramphenicol and penicillin G against experimental relapsing fever. PAUL E. THOMPSON and MARY C. DUNN (introduced by A. C. BRATTON, JR.), *Research Labs., Parke, Davis and Co., Detroit, Mich.* Chloramphenicol (chloromycetin, Parke, Davis & Co.) exhibited marked antispirochetal activity when tested against standardized infections of *Borrelia novyi* in mice (using slight modifications of the methods of Richardson, Walker, Loeb and Miller, *J. Pharmacol. and Exp. Therap.* 85 (1) 23, 1945). Evidence of specific activity was indicated by suppression of the blood infection and

reduction of mortality among infected animals. Following these observations in preliminary studies, the activity of chloramphenicol was compared on a weight basis with that of crystalline penicillin G in a series of parallel experiments. Chloramphenicol was approximately $\frac{1}{4}$ as active as penicillin G in suppressing blood infections. However, comparison of the protective action of the drugs against lethal doses of spirochetes revealed that chloramphenicol was approximately $2\frac{1}{2}$ times as active as penicillin G.

Pharmacological evaluation of Trimeton, 1-Phenyl-1-(2-pyridyl)-3-N,N-dimethylpropylamine, and Chlor-Trimeton, 1-(p-Chlorophenyl)-1-(2-pyridyl)-3-N,N-dimethylpropylamine. RICHARD TISLOW, ANNETTE LABELLE, ALOIS J. MAKOVSKY, MARY ANN GRIFFITH REED, MARGARET D. CUNNINGHAM, JANE F. EMELE, ARNOLD GRANDAGE and RUTH J. M. ROGGENHOFFER (introduced by H. B. HAAG), *Biological Research Labs., Schering Corporation, Bloomfield, N. J.* Chlortrimeton and Trimeton (*Abstr. 1948 Chicago Meeting, Am. Chem. Soc.*, p. 4K), Pyribenzamine and Benadryl were compared for antihistamine potency (preventing death from 1.1 mg/kg histamine hydrochloride injected intravenously 1 hour later) and toxicity in guinea pigs. In dogs, Chlor-Trimeton potentiated the epinephrine increase of blood pressure, inhibited the depression of histamine but not of arecoline. Lethal doses of the antihistamine compounds upon intravenous infusion at 25 mg/kg/hour were

Compound	No of Dogs	Lethal Dose (mg/Kg)	σ
Trimeton hydrochloride	4	89.0	± 12
Chlor-Trimeton maleate	3	97.6	± 2
Chlor-Trimeton hydrochloride	3	58.8	± 7
Pyribenzamine	4	48.8	± 14
Benadryl	2	91.7	± 10

Taking the therapeutic index of Pyribenzamine as 1, the value for Trimeton is 4 and Chlor-Trimeton maleate 50. The chlorination of Trimeton in the phenyl ring results in a twenty fold increase in activity without any appreciable change in toxicity. This is in contrast to Benadryl, Pyribenzamine and Thienylene, the halogenation products of which show no such marked increase in activity.

Effect of convulsant and anticonvulsant agents on the activity of carbonic anhydrase. CLARA TORDA and HAROLD G. WOLFF, *New York Hospital and the Depts. of Medicine (Neurology) and Psychiatry, Cornell Univ. Medical College, New York City*. The concentration of carbon dioxide (carbonic acid, bicarbonates) available for metabolic processes in the brain may be an essential factor in the induction and prevention of convulsive seizures according to Lennox and collaborators. The effect of certain convulsant and anticonvulsant

agents on the activity of carbonic anhydrase was investigated to ascertain whether these substances exert any effect on the carbon dioxide uptake and release as effected by this enzyme. The activity of carbonic anhydrase was inhibited in the presence of the convulsant agents used (acetylcholine, camphor, dichloro-diphenyl-trichloro-ethane, digitoxin, pentamethylene tetrazol, picrotoxin, scilliroside, strychnine, and ouabain) in concentrations of $1 \times 10^{-4}M$ and less, the greatest inhibition being, on the average, 54%. The activity of carbonic anhydrase increased in the presence of the anticonvulsant agents used (hydantoin, methyl-phenyl-ethyl hydantoin, and phenobarbital) in concentrations of $1 \times 10^{-4}M$ and less, the greatest increase of activity being, on the average, 50%. The results presented suggest that convulsant agents, by inhibiting the activity of carbonic anhydrase (from blood and probably from brain), decrease the removal of metabolic endproducts from brain. Furthermore, anticonvulsant agents, by increasing the activity of carbonic anhydrase (from blood and probably from brain), increase the removal of the above mentioned metabolic products from brain.

Determination of beryllium in biological material T. Y. TORIBARA, W. F. NEUMAN, A. L. UNDERWOOD and M. W. CUCCI (introduced by H. C. HODGE) *Dept of Radiation Biology of the Univ of Rochester, Rochester, N. Y.* Beryllium administered intravenously is very toxic, the LD_{50} is approximately 0.36 mg/kg. Thus for distribution and excretion experiments, not more than 0.2 mg/kg can be administered. At such a dose level, many tissues may be expected to contain 0.1 microg/g or less. Thus, any procedure, to be useful, must detect with accuracy much less than one microgram. Chemical methods are not as sensitive as the spectrographic method for the determination of beryllium, but they are adequate for many purposes. Existing methods are too sensitive to pH, salt concentration and the presence of other metals. Because of these reasons and also because of the small amounts being sought, the isolation of beryllium is just as important as the determination. This work seeks to improve both the separation and the method of determination. One fluorometric and 5 colorimetric methods of determination and procedures for isolation of small amounts of beryllium will be discussed.

Synergistic effect of sodium acetate and ethanol in antagonizing sodium fluoroacetate (1080) poisoning in mice W. W. TOURTELLOTT (by invitation) and J. M. COON. *Univ of Chicago Toxicity Lab and the Dept of Pharmacology, Univ of Chicago, Chicago, Ill.* Following the suggestive results of Hutchens et al (*J Pharmacol*, in press) Carworth farm mice weighing 18-22 gm were poisoned with 1080 subcutaneously and immedi-

ately treated intraperitoneally with ethanol, sodium acetate, or sodium acetate dissolved in ethanol. The LD_{50} of the 1080 powder used in these experiments was found to be 17.0 mg/kg. The most effective combination of ethanol and sodium acetate found for antagonizing 1080 poisoning was 2.0 gm (16% solution) to 3.0 gm (24% solution) of sodium acetate/kg injected with 1.6 gm of ethanol (20% by volume)/kg. This saved 90-100% of the mice poisoned with 10 LD_{50} of 1080. When poisoned mice were treated immediately with 1.6 gm/kg of ethanol or 3.0 gm/kg of sodium acetate alone, then the LD_{50} of 1080 was raised by a factor of about 3 (54.0 mg/kg) or a factor of about 4 (63.0 mg/kg), respectively. However, when poisoned mice were treated immediately with 3.0 gm/kg of sodium acetate dissolved in 1.6 gm/kg of ethanol, then the LD_{50} was raised by a factor of 12 (201.0 mg/kg). These data indicated that ethanol and sodium acetate acted synergistically in antagonizing 1080 poisoning. When treatment was given at 3, 7, 10, and 22 minutes after poisoning, the LD_{50} was raised by factors of approximately 8, 4, 3, 2, respectively. The effect of treating poisoned guinea pigs, rabbit, and dogs with ethanol-acetate solutions and barbiturates will be discussed.

Influence of ethyl chloride spray on deep pain and ischemic contraction of skeletal muscle J. TRAVELL, and S. H. RINZLER, (by invitation) *Dept of Pharmacology, Cornell Univ Medical College, and Cardiovascular Research Unit of Beth Israel Hospital, New York City.* Since painful skeletal muscle spasm may be relieved by ethyl chloride spray, we investigated its effects on deep pain and muscular endurance during ischemia produced by a cuff on the upper arm. Endurance was measured by the number of times the subject could close the fingers during ischemia. A constant rate of 30 isotonic contractions per minute was maintained by a metronome. 1) After a series of control measurements, one arm was sprayed with ethyl chloride for 5 minutes and endurance determined again on both arms. Tests were run 20 minutes apart, when determined at such intervals on the same day, endurance remains relatively constant. Amounts of ethyl chloride used did not cause frosting, cold pain, or loss of cutaneous sensibility to pinprick. Results indicate that one such application of spray may double muscular endurance during ischemia. 2) After endurance was determined for 1 arm, without releasing pressure in the cuff, the forearm was similarly sprayed with ethyl chloride for 1 minute and contractions resumed until pain again became intolerable. The procedure was repeated on the other arm, except that a rest period of 1 minute was substituted for spraying. Data show that ethyl chloride spray, applied during ischemia at the limit of endurance,

markedly lessens pain and enables the subject to perform muscular contractions markedly in excess of the increment possible after rest alone. These effects obviously cannot be attributed to circulatory changes in muscle. Similar effects were not secured by one minute immersion of the forearm in cold water (12–20°C) during ischemia. Results suggest that impulses from superficial structures play an important role in deep pain perception and skeletal muscle function.

Thiouracil administration and thyroidectomy on experimental polyarthritis of rats HELEN B. TRIPI, WILLIAM C. KUZELL, and GRACE M. GARDNER (introduced by P. J. HANZLIK) *Dept. of Pharmacology and Therapeutics, Stanford Univ. School of Medicine, San Francisco 15, Calif.* Albino rats administered 0.1% thiouracil in the diet for periods up to 233 days developed hyperplastic thyroids with nodular hyperplasia. When infected with the L-4 strain of pleuro-pneumonia-like organisms these animals developed a more severe degree of polyarthritis than did the controls, and showed a higher mortality. Thyroidectomized albino rats which had an average basal metabolic rate of only 58% of normal (the same as for the thiouracil-medicated rats) when infected with the same microbes developed an arthritis which was no worse than that in the controls. Other rats poisoned with agents chemically and physically different from thiouracil, namely, arsenic trioxide, isopropyl alcohol and phenobarbital, showed no increase in severity of polyarthritis due to these microbes. Thus, the increased severity of this experimental polyarthritis in thiouracil-medicated rats is believed to be due to some peculiar intrinsic action of thiouracil.

Algesimetry in the study of procaine anesthesia PAUL E. TULLAR (introduced by THEODORE KOPFANYI) *Dept. of Pharmacology, Georgetown Univ. School of Medicine, Washington, D. C.* It was possible to differentiate between the drug factor (D.F.) and the pressure factor (P.F.) in infiltration anesthesia by the combined use of several testing methods. Three types of stimuli (radiant heat, electric and mechanical) were employed to determine the degree, duration, and other features of procaine-infiltration analgesia in man. Pain sensation is measured a) in seconds required to produce a sharp burning pain and withdrawal of the finger with a modified Wolff-Hardy stimulator, b) in cm. distance between the primary and secondary coils of a Harvard Inductorium, and c) in units pressure required to produce sharp 'pricking' pain with a calibrated, spring driven aesthesiometer. At no time were stimuli in excess of 30 seconds for burning pain, 4 cm. for faradic shock, or 10 gm. needle pressure permitted, in order to avoid burn. It was found that stimuli of the above maximal intensities did not interfere with the repeated use

of the nail-base areas. After establishing normal responses, test solutions (0.2 to 0.25 cc.) were injected subcutaneously into the sensitive nail-base of eleven subjects for a total of 24 individual tests. The injection of procaine-HCl (1% and 2%) resulted in increased thresholds to all 3 types of stimuli. The anesthesia was of short duration and showed gradual return to normal except in the case of radiant heat where marked hyperalgesia preceded the ultimate return to normal as occurred in a majority of instances. Injection of normal saline resulted in marked anesthesia to mechanical and electrical stimuli, but showed no or little analgesia to radiant heat stimulation.

Changes in blood volume during prolonged pentothal anesthesia JAMES E. TUREMAN (by invitation), A. H. MALONEY, WALTER M. BOOKER and CLAUDIA M. RATLIFF (by invitation) *Dept. of Pharmacology, College of Medicine, Howard Univ., Washington, D. C.* In connection with our work on prolonged pentothal sodium anesthesia it has been observed that the blood picture follows a more or less definite pattern which tends to represent a hemodilution. An attempt is being made to determine if the hemodilution is real or relative and the possible mechanism. At this time 38 experiments have been completed, using 6 rabbits and 32 mongrel dogs. The dogs were divided into 3 groups, a group on normal diet, a group on high carbohydrate diet, and a group on high protein diet. Initial blood samples were taken, following which dogs were anesthetized with pentothal sodium and maintained in surgical anesthesia for an average of 3 hours. Hemoglobin and/or hematocrit was determined at $\frac{1}{2}$ hour intervals in some instances and in others at 1 hour intervals. Hemoglobin decreased an average of 1.7 gm. % during the first hour then tended to increase until the end of the experiment. The hematocrit decreased an average of 6% during the first hour and increased similarly as the hemoglobin. At the end of the experiments the values approached or equaled the initial values. There was no apparent difference in the groups. In an attempt to discover the mechanism and determine if these results were real or relative, tissue space by the thiocyanate method and plasma volume by the 1824T dye method were determined. In 6 experiments it appears that fluid is drawn from the tissue spaces.

Adrenolytic activity of a number of N-phenylisopropyl-beta-haloethylamines GLENN E. ULLYOT (by invitation), JAMES KERWIN (by invitation), EDWIN J. FELLOWS and EDWARD MACKO (by invitation) *Research Division, Smith, Kline and French Labs., and Dept. of Pharmacology, Temple Univ. School of Medicine, Philadelphia, Penna.* Substances with the following structure were compared with 'Dibenamine' for their effect after intravenous administration on the pressor

action of epinephrine in cats anesthetized with pentobarbital sodium $R-N-CH_2-CH_2-X$ Ac-

tivity comparable with that of 'Dibenamine' was noted when R = phenylisopropyl and R_1 = allyl or isobutyl but where R = allyl or isobutyl but where $R \times$ phenylisopropyl and R_1 = ethyl or isopropyl, the compounds were less active. In the case of the derivative in which R_1 = benzyl and R = unsubstituted phenylisopropyl, activity greater than that of 'Dibenamine' was obtained. The same was true when R_1 = benzyl and R = p-methoxy-, p-hydroxy-, 3,4-dimethoxy-, or 3,4-dihydroxy-phenylisopropyl.

Anticonvulsive properties of myanesin K UNNA and A KAPLAN (by invitation) *Dept of Pharmacology, Univ of Illinois College of Medicine, Chicago 12, Ill*. The anticonvulsive effect of myanesin was studied in 500 mice treated with either strychnine or metrazol, or subjected to maximal seizures induced by electroshock. Myanesin was administered subcutaneously in doses ranging from 100 to 500 mg/kg, 10 minutes before the convulsive agent. A dose of 500 mg/kg represents the paralyzing dose. The observation of Berger and Bradley that strychnine convulsions are effectively antagonized was confirmed. Both mortality and severity of the convulsions caused by strychnine (175 mg/kg i.p.) were markedly reduced. The mortality of the mice treated with metrazol (90 mg/kg i.p.) was less effectively reduced. The metrazol seizure of mice treated with 100 or 200 mg/kg of myanesin, however, was at least as severe as in the controls and often prolonged. The tonic extensor phase of metrazol convulsions, in which most of the control animals die, was eliminated by myanesin; death of the myanesin-treated mice was delayed. The electroshock (25 mA for 0.3 seconds by eye-electrode) caused typical seizures in 89% and a mortality of 33% of the control animals. None of the myanesin-treated animals died from electroshock. The pattern of the seizures was changed by myanesin (200 mg/kg) in that the tonic flexor-extensor phase was abolished, and only clonic convulsions of a much more violent nature than in the controls were observed.

Elimination of d-tubocurarine in the rat E F VAN MAANEN (introduced by OTTO KRAYER) *Dept of Pharmacology, Harvard Medical School, Boston, Mass*. Rats were anesthetized with urethane. Contractions of the gastrocnemius muscle, maximally stimulated through the sciatic nerve, were recorded. The total curarizing dose was measured at different rates of administration of d-tubocurarine. The amount of fluid injected per hour was 4.75 cc. It was found that, when d-tubocurarine was administered at a rate of 1000 γ /hr/kg rat or more approximately 70 γ /kg rat was neces-

sary for complete curarization of the gastrocnemius muscle. Decreasing the rate of administration resulted in an increase in the amount of d-tubocurarine necessary for total curarization. It was impossible to obtain complete curarization, when less than 80 γ /hr/kg rat was administered, even though the injection lasted for 5 hours or more. In nephrectomized rats the total curarizing dose differed very little from that of normal rats, when 150 γ /hr/kg rat or more was administered. However, when less than 150 γ /hr/kg rat was injected the total curarizing dose was less than that of normal rats. Complete curarization was obtained in nephrectomized rats when the rate of administration was as low as 60 γ /hr/kg rat.

Secretion of cortical hormone by the isolated adrenal MARTHE VOGT (introduced by H B VAN DYKE) *Pharmacological Lab, Univ New Buildings, Edinburgh, Scotland*. The isolated adrenal of a dog, perfused with blood by means of a Dale-Schuster pump, secretes cortical hormone in quantities detectable by biological assay on adrenalectomized rats exposed to cold. The rate of secretion is not much lower than that of the gland *in situ* during the course of an abdominal operation. It is not abolished by perfusing with blood from a hypophysectomized donor, and is immediately enhanced by the administration of corticotrophic hormone. The rate of secretion is unaffected by a number of metabolites (glucose, lactic acid, amino acids), but is augmented by adenosine-tri-phosphate and by creatine phosphate. Inorganic phosphate has no such action. These effects may be connected with the energy requirements of the synthetic processes continually going on in the gland. Another factor found to increase the output of cortical hormone is a raised concentration of potassium in the plasma. In order to obtain an acceleration of cortical secretion which can be detected by the assay employed, the plasma potassium has to be increased considerably, i.e., to values which may occur in adrenalectomized dogs, but not in normal animals. It is interesting that this effect is obtained in the absence of the pituitary, and it would be desirable to know whether smaller rises in the rate of secretion, such as cannot at present be established by direct biological assay of the hormone in blood, would result from more physiological variation in the potassium level of the plasma.

Therapeutic efficiency of various dosage schedules of oxophenarsine in experimental trypanosomiasis HARRY A WALKER, SUSANNE WILSON (by invitation), and A P RICHARDSON *Dept of Pharmacology, Emory Univ School of Medicine, Emory Univ, Georgia*. Recently, the relation of dosage schedule to the therapeutic effect of a number of chemotherapeutic agents in the treatment of experimental bacterial and protozoal infections

has been investigated in order to establish optimal dosage regimes. This report concerns the relative therapeutic efficiency of dosages of oxophenarsine given by single and multiple intraperitoneal injections against *Trypanosoma equiperdum* infections in the mouse. Previously it has been demonstrated with this infection in the rat that arsenoxide (oxophenarsine) produces a prompt trypanocidal effect as indicated by a decrease in parasite density of the peripheral blood within a period of 30 minutes. In our experiments mice were infected intraperitoneally with an inoculum of 100 million parasites/kg of body weight and remained untreated until 24 hours after inoculation. From stained thin smears made every 5 minutes after a single intraperitoneal injection of oxophenarsine it was found that within 10 minutes a decrease in parasite density occurred. Within 45-60 minutes the maximum effect was obtained. On the basis of the above data and the fact that the arsenic content of the blood after an intravenous injection of oxophenarsine falls abruptly to a low level by the end of 1 hour, the ED_{50} of oxophenarsine given intraperitoneally in 10 equal doses every 1.5 hours starting 24 hours after inoculation was determined and found to be 0.30 mg/kg. The ED_{50} of a single dose injected 24 hours after inoculation was 0.15 mg/kg. The data indicate that a single dose of oxophenarsine exerts a significantly greater therapeutic effect than that produced by the same dosage given in 10 equal doses at intervals of 1.5 hours.

Cardiac and calorogenic actions of dicumarol and dinitrophenol. R. P. WALTON, C. B. HANNA (by invitation), R. P. PRYSTOWSKY (by invitation), and J. S. LEARY (by invitation). *Dept of Pharmacology, Medical College of South Carolina, Charleston, S. C.* Calorogenic and cardiac actions of dicumarol at high dose levels have been described respectively by Wakim, Chen and Gatch (*S. G. & O.* 76:323, 1943) and Carlson and Seager (*Fed. Proc.* 7:210, 1948). The experiments reported here were aimed at defining the nature of the cardiac action. The contractile force of a section of the right ventricle was determined directly in open-chest dog preparations along with other observations of systemic changes. Dicumarol was administered in doses of 10 to 100 m.p.k. by i.v. infusion over periods of 30 min. Doses at the low extreme had no clear effect while those at the high extreme quickly produced terminal fibrillation with little evidence of contractile force stimulation. Intermediate doses in about 60% of the trials produced first slight to moderate depression followed by distinct to marked increases in contractile force, stroke amplitude, heart rate, arterial pressure, external respiratory movements and rectal temperature. The contractile force increases usually reached a maximum about 60 min after

the start of the infusion. For the most part, effects developed at parallel rates. In a few instances, however, the cardiotonic action clearly preceded the temperature rise and also was characteristically obtained in experiments in which the rectal temperature rise was prevented by the use of ice packs. Moderate increases in venous pressure were considered insufficient to account for all of the increases in contractile force. A closely similar group of responses were obtained with dinitrophenol in the dose range of 10 to 20 m.p.k. Distinct contractile force increases of the same order were obtained by the application of diathermy. Perfusion of isolated rabbit hearts with dicumarol or dinitrophenol produced marked depressant effects preceded, at times, by stimulation. In the open-chest experiments and in intact dogs receiving 250 to 400 m.p.k. dicumarol orally ECG records commonly showed T-wave reversal and deflection of the RS-T segment but did not usually show A-V dissociation until near the terminal stages.

Effect of various lactones and of veratrine on the mammalian heart. R. P. WALTON, M. DEV. COTTEN (by invitation), and O. J. BRODIE (by invitation). *Dept of Pharmacology, Medical College of South Carolina, Charleston, S. C.* Contractile force changes of a section of the right ventricle were determined in open-chest vagotomized dogs along with ECG and arterial pressure recordings. Four lactones, previously shown to have digitalis-like effects on the cold-blooded heart, had no stimulant effects on the mammalian heart *in situ*. Administered by i.v. infusion over periods of 30 min, the compounds were psi-santonin, 30 to 150 m.p.k., 1-ascorbic acid, 50 to 250 m.p.k., beta-gamma-angelica lactone, 400 to 800 m.p.k., di-lactone of pulvinic acid, saturated solution in saline, 20 cc/kg. The first 3 of these compounds produced significant depression suggestive of that obtained with alcohol. The di-lactone of pulvinic acid had no clear effect, doses up to 2 m.p.k. were injected in dioxane solution with, however, immediate precipitation.—The commercial *N.F.V.* mixture of alkaloids termed 'veratrine' was administered by infusion as above, also, by immediate injections, doses were alternated with epinephrine both before and after dibenamine. Pressor effects and cardiac stimulation with veratrine and epinephrine were generally similar although the effects of veratrine were more sustained. Dibenamine blocked effects of both drugs in a parallel manner. In contrast to epinephrine, veratrine, in small doses frequently produced temporary depression and, in larger doses, a greater tendency to fibrillation, also, stimulant effects more frequently diminished on repeated injection. Veratrine doses of 350 gamma/kg corresponded approximately to epinephrine doses of 5 gamma/kg. Cardiac stimulant effects of veratrine were accompanied by strong skeletal

muscle movements which were disturbing if not blocked by curare ECG effects consisted mainly in the R and S-wave voltage changes which usually occur with left axis deviation, frequent reversal of T-wave and, in the terminal stages, ventricular ectopic beats with frequently a bi-directional rhythm A-V dissociation did not commonly occur until near the terminal stages In isolated rabbit heart preparations, veratrine concentrations 10 to 20 times those of epinephrine produced generally similar effects and could be successively repeated several times

Pharmacological studies on 2-[N-p'-tolyl-N-(m'-hydroxyphenyl)-aminomethyl-]imidazoline hydrochloride (C-7337) M R WARREN, R A WOODBURY and J H TRAPOLD (by invitation) *Division of Pharmacology, Univ of Tennessee, Memphis, Tenn* 2-[N-p'-tolyl-N-(m'-hydroxyphenyl)-aminomethyl-]imidazoline hydrochloride (C-7337) has been shown to be an effective adrenergic blocking agent in dogs following oral and intravenous administration Its onset of action is more rapid than that reported for Dibenamine after intravenous injection but its duration is shorter The pressor response elicited by anoxia or the intravenous injection of carbaminoylcholine in atropinized dogs is converted into a depressor response Doses which cause 'epinephrine reversal' have no significant effect on the depressor action of acetylcholine and histamine Ephedrine sulfate given intravenously will combat the hypotensive action induced by rapid injection of C-7337 and decreases the duration of its adrenolytic effect Isolated uteri from estrogen-treated rabbits are stimulated by weak concentrations but only inhibition is obtained with greater concentrations Contractions elicited by histamine, epinephrine, pitocin and pitressin are likewise inhibited Spontaneous contractions of the isolated ileum of the rabbit, cat and rat are suppressed as are contractions induced by barium chloride, acetylcholine, and pitressin This inhibitory action on the intestine is not abolished by atropine Acute toxicity work in dogs indicates that approximately 100 mg/kg, administered twice daily, are required to kill 50% of the animals within a period of 1 week Single doses as large as 500 mg/kg failed to prove lethal Chronic oral administration of C-7337 in doses up to 50-60 mg/kg twice daily for three months caused no appreciable gross toxic manifestations with the possible exception in young or pregnant animals

Isomers of methadon and isomethadon and respiration of brain homogenates DANIEL T WATTS, (introduced by C L GEMMILL) *Dept of Pharmacology, Univ of Virginia Medical School, Charlottesville, Va* The effect of d-, l-, and d,l-methadon and d-, l-, and d,l-isomethadon on the oxidation of glucose, succinate and ascorbate by

fortified brain homogenates was investigated A Warburg apparatus was used to determine simultaneously in triplicate the oxygen uptake in control vessels and in vessels containing the d-, l- and d,l-methadon or isomethadon Oxygen uptake, expressed as percentage inhibition (O_2 uptake in control vessels, minus uptake in vessels with drug, divided by control uptake) was as follows

Substrate	Drug Conc. Molar	Methadon			Isomethadon		
		d,l	d-	l	d l	d	l-
Glucose	0 005	65	50	56	76	55	62
Succinate	0 003	—	—	—	57	57	60
Succinate	0 007	74	66	76	—	—	—
Ascorbate	0 005	53	53	76	84	82	86

The observed decrease in O_2 uptake may be due to a general enzymatic inhibition or to a specific block at the cytochrome-cytochrome oxidase level Inhibition of ascorbate oxidation which requires only the catalytic action of cytochrome-cytochrome oxidase indicates blockage occurs at this level

Effect of local anesthetics on respiration of brain homogenates DANIEL T WATTS, (introduced by C L GEMMILL), *Dept of Pharmacology, Univ of Virginia, Medical School, Charlottesville, Va* The effect of selected local anesthetics on the oxidation of glucose, succinate and ascorbate was investigated The homogenates were diluted to reduce endogenous activity to a minimum and then reinforced with as many factors as possible to obtain maximum oxygen uptake for the substrate under investigation Additional cytochrome c, calcium and aluminum ions were added for succinate and ascorbate oxidation Hexose diphosphate, adenosine triphosphate, diphosphopyridine nucleotide, cytochrome c, nicotinamide and magnesium ions were added for glucose oxidation Oxygen uptake was measured with Warburg manometers simultaneously in duplicate for controls and for vessels containing the drugs at a final concentration of 0 005 M Oxygen uptake expressed as per cent inhibition was as follows

	Glucose	Succinate	Ascorbate
Cocaine HCl	32	9	0
Procaine HCl	22	11	9
Metycaine HCl	46	8	4
Pontocaine HCl	64	44	36
Nupercaine HCl	74	95	68

In a further attempt to isolate the point of blockage by the local anesthetics it was found that nupercaine a) did not inhibit the reduction of methylene blue by succinate and homogenate, b) inhibited the oxidation of reduced cytochrome by homogenate in presence of oxygen, c) inhibited the reduction of oxidized cytochrome c by homogenate and succinate when the cytochrome oxidase

was inhibited by cyanide. These observations indicated that the cytochrome oxidase and the factors necessary for the reduction of cytochrome *c* are sensitive to the action of nupercaine.

Cardiac-active principles in osage orange. R A WAUD, C W GOWDER (by invitation) and J S LOYNES (by invitation) *Dept of Pharmacology, Univ of Western Ontario, London, Canada.* It has been shown previously by one of us (RAW) that Osage Orange contains a substance or substances which cause marked augmentation of the isolated hypodynamic frog's heart when perfused through the vena cava. Prolonged augmentation was also shown in a large percentage of isolated rabbit hearts perfused by the method of Langendorff. The augmentation was not accompanied by changes in heart rate nor by changes in conduction. Systolic standstill did not occur. These principles have been investigated further and we believe that a large part of the cardiac activity is due to a phytosterol which occurs in the non saponifiable fraction of the oil contained in the Osage Orange. This sterol has been isolated and obtained in crystalline form. Definite activity is shown by a concentration of 1/200,000 of this crystalline substance. From the work of Danilewsky in 1907 on the actions of cholesterol on the frog's heart one might expect the results we have described because of the close structural relationships between the plant sterols and cholesterol. We have repeated the work with cholesterol and in addition have tested the activity of several other sterols. Ergosterol has a similar but weaker action. Similar activity was found in the California Orange.

Absorption and distribution of isopropyl alcohol. JOAN WAX (by invitation), FRED W ELLIS, and ARNOLD J LEHMAN *Dept of Pharmacology, School of Medicine, Univ of North Carolina, Chapel Hill, N C.* As part of a systematic pharmacologic study of isopropyl alcohol (IPA) the gastrointestinal absorption and tissue distribution of this substance was investigated. In pentobarbitalized dogs *in situ* stomach and/or intestinal loops were isolated, and IPA absorption was studied as affected by site and extent of absorbing surface, concentration, time, successive doses, and systemic ethyl alcohol. Absorption of IPA occurred from all portions of the digestive tract, most rapidly in the jejunum and least in the stomach. During a 30-minute absorption period IPA was distributed to the spinal fluid, brain, liver, kidney and skeletal muscle. Spinal fluid and blood concentrations were approximately equal, but there was no constant relationship between tissue and blood concentrations. Increased absorption area resulted in increased tissue concentration, but did not influence total absorption. The percentage absorption was not markedly affected by the concentration of IPA although at the site of

highest absorption (jejunum), 10% strength was absorbed significantly better than 5%, 50%, and 99%. Previous absorption of IPA from intestinal loops did not influence subsequent absorption from adjacent loops. Ethyl alcohol administered intravenously markedly decreased the intestinal absorption of IPA.

Fate of certain antihistamines. E LEONG WAY, ROBERT E DAILEY (by invitation) and DONALD L HOWIE (by invitation) *Dept of Pharmacology, The George Washington Univ School of Medicine, Washington, D C.* Certain antihistamines have been successfully determined in biologic tissue by application of the Brodie methyl orange technique. A high degree of specificity was obtained when the method was modified for determining tripeleannamine (pyribenzamine) and phenindamine (thephorin). Tripeleannamine was used as the standard for comparison with other agents. In rats fasted for at least 18 hours, after a single oral dose of 100 mg/kg about 35% of the total dose was recovered in the gastro-intestinal tract after 2 hours and about 5% after 4 hours. After intraperitoneal administration of tripeleannamine to rats or guinea pigs high concentrations were obtained in the spleen, lung, liver and kidney. Concentrations in the brain were almost as high and low levels were found in muscle, heart and blood. Preliminary results with phenindamine indicate that its distribution follows somewhat the same pattern as that for tripeleannamine. After 3 daily doses of either tripeleannamine or phenindamine for several days, slight or no levels were detected in the tissues after 24 hours, indicating little or no storage of the compounds. Evidence that both compounds are rapidly metabolized is indicated by the fact that only slight amounts of either compound were recovered in excreta after parenteral administration. Preliminary *in vitro* results on tripeleannamine indicate that the detoxication site is the liver.

Fate of dl-methadon. E LEONG WAY, CHEN-YÜ SUNG (by invitation) and WILLIAM P MCKELWAY (by invitation) *Dept of Pharmacology, The George Washington Univ School of Medicine, Washington, D C.* The fate of dl-methadon was investigated in rats by application of Brodie's methyl orange technique. The method was modified to give a high degree of specificity for methadon in biological tissues. In fasted rats, about 25% of the total methadon dose given orally was recovered in the gastro-intestinal tract after 2 hours. The compound was found to be firmly bound by all tissues, especially muscle. After intraperitoneal administration of methadon highest concentrations were found in the lung, liver, kidney and spleen. Low levels were present in blood, brain, muscle and heart. After injections of methadon 2 or 3 times daily for several days, there was little

or no methadon in tissues removed 24 hours after the last dose, indicating that prolonged storage of methadon does not occur. Only a small fraction of the total administered dose was recovered in the urine as methyl orange reactant. It was also found that *in vitro*, liver and kidney slices metabolized methadon within 4 hours to substances which are not measured by the methyl orange technique.

Vasoconstrictor activity of epinephrine, ephedrine and a new sympathomimetic diamine 1-(*m*-hydroxyphenyl)-*N*²-methylethylene diamine (NU-1683) HOWARD WAYNE (by invitation), LEWIS FRANKLIN (by invitation), and HAROLD D. GRLEN, *Dept. of Physiology and Pharmacology, Bowman Gray School of Medicine of Wake Forest College, Winston-Salem, N. C.* Lehmann and Randall recently described a series of sympathomimetic diamines (*J. Pharm. and Exp. Therap.* 93: 114, 1948). We compared the vasoconstrictor activity of one of these, NU-1683, with that of epinephrine and ephedrine by injections of each into the femoral artery of dogs while measuring the venous outflow with a modified Gaddum-type meter connected to the femoral vein. 1 μ gm of epinephrine reduced flow by 15-78% (av. 49%) in 35 injections in 6 dogs. Latency of response was 20-30 seconds, minimum flow occurred approximately 50 seconds later and lasted 10-50 seconds. Duration of response was 2.8 min (range 1.3-6.7 min). Tachyphylaxis did not occur. 1-3 mg of NU-1683 reduced flow 24-78% (av. 45%). Minimum flow lasted 20 seconds, duration of response was 4.2 minutes (range 1.3-8.5 mins) in 13 injections in 7 experiments. Tachyphylaxis did not occur. 1 mg of ephedrine reduced flow 25% (range 15-43%) in 6 injections in 3 experiments. Minimum flow lasted 13 seconds. Duration of response was 0.9 minutes (range 0.5-1.2 mins). Tachyphylaxis did occur. With each drug the latent period of response and times for occurrence of minimum flow were about the same. Sufficient data is not yet available to predict the dose response curves for these drugs. A detectable reduction of flow (10%) is usually produced by 0.1/gm of epinephrine, 0.1 mg of NU-1683 and 0.1 mg of ephedrine, and an almost complete cessation of flow (90% reduction) by 3-10 gm of epinephrine and 10 mg of NU-1683.

Separation by fluoroacetate of energy sources for smooth muscle contraction JAMES R. WEEKS (by invitation) and MAYNARD B. CHENOWETH, *Dept. of Pharmacology, Univ. of Michigan, Ann Arbor, Mich.* Contraction of rabbit jejunum segments in oxygenated Krebs-Henseleit solution is maintained equally well by 0.005 M glucose or sodium acetate. Addition of sodium fluoroacetate (FA) decreases contraction amplitude. Communication with Dr. Alfred Farah during early phases of our study disclosed that muscles contracting in

glucose are more resistant to FA than in sodium acetate. This has also been found true for acetate in the form of monoacetin, although this is the only effective *in vivo* FA antagonist. By use of various concentrations of FA acting on jejunal segments in 0.005 M glucose it has been found that even at very high concentrations of FA reduction of contraction amplitude below about 35% of initial amplitude does not occur. In 0.005 M acetate FA in similar high concentrations reduces contraction almost to zero. Addition of glucose to 0.005 M returns contraction to the approximate level expected had glucose been present initially. Yet at low concentrations of FA acetate is a better antagonist than glucose. These findings may be harmonized by presuming that intestinal muscle obtains energy aerobically from breakdown of glucose to pyruvate and subsequently from syntheses in the tricarboxylic acid cycle involving acetate. When acetate as the sole available substrate is blocked from entry into the cycle by high concentrations of FA, contraction ceases, while low concentrations of FA are unable to produce a block in presence of excess acetate. In presence of glucose energy for partial contraction is available despite presence of FA block of acetate.

Mechanism of cardiac injury in experimental hypothermia DAVID WEINER, KURT LANGE and MICHAEL M. A. GOLD (introduced by M. G. MULINOS), *Dept. of Medicine, New York Medical College, New York City*. Rabbits suffering from lowering of body temperature show a reduction in heart rate directly proportional to the fall in body temperature. The P-R interval and the QRS complex show a prolongation roughly proportional to the fall in body temperature. The relative duration of electrical systole as expressed by Bazett's formula reveals a prolongation which becomes relatively greater as body temperature decreases. The very marked S-T segment and T wave changes under such conditions show individual differences in extent and localization in both rabbits and dogs. The changes in rate and conduction are exclusively the result of the direct effect of cold. The prolongation of electrical systole is partly the result of cold directly on the muscle fibres and partly the result of anoxia due to lowered oxygen dissociation. The T wave changes are exclusively the result of anoxia. The anoxic nature of the S-T segment and T wave changes as well as part of the prolongation of electrical systole is proved by the fact that increasing the oxygen dissociation of the blood by acidification reverses them to normal. Acidification of the blood of uncolled rabbits and dogs does not change the EKG. Anoxemia plays no role in the production of any of the changes seen in the heart with exposure to cold. We are dealing with anoxia without anoxemia.

Fate of dicoumarol in man MURRAY WEINER

(by invitation), JULIUS AXELROD (by invitation), SHEPARD SHAPIRO (by invitation) and BERNARD B BRODIE *Depts of Biochemistry and Medicine, New York Univ College of Medicine, and New York Univ Medical and Research Services, Goldwater Memorial Hospital, New York, N Y* A method for the estimation of dicoumarol in biological material has been devised. It is specific in that neither normal biological material nor metabolites of the drug are included in the measurement. With this method, those factors which affect the plasma concentration of the drug such as absorption, excretion, metabolism and tissue localization are being studied. Only traces of dicoumarol were found in the urine after its administration, indicating the almost complete metabolism of the drug in the body. The rate of metabolism is slow and varies with the dose. It varies from about 25% per day at the upper therapeutic plasma levels to over 75% per day at low plasma levels. There are wide variations in the rate of transformation in different individuals, even at similar plasma levels. The drug is highly localized on plasma proteins (about 99% plasma binding) and in various tissues. Its low concentration in plasma water explains in part, its low transformation rate. The rate of absorption of the drug from the gastrointestinal tract is slow and varies with the individual and with the dose. Thus in the same individual a dose of one mg/kg yielded a peak plasma concentration within 6 hours while a dose of 8 mg/kg did not yield a peak level until more than 24 hours. The relationship between dicoumarol concentration and prothrombin time elevation is being studied in the hope that safer dosage with the drug may be achieved by following plasma levels.

Influence of xanthopterin on the folic acid content of liver, *in vitro* ARNOLD D WELCH, EVELYN M NELSON (by invitation) and MARILYN F WILSON (by invitation) *Dept of Pharmacology, School of Medicine, Western Reserve Univ, Cleveland,*

The activity for *L. casei* or *S. faecalis* of rat liver homogenate or cell-free extract is increased by incubation at pH 7, 37°C, if added promptly, the increase is augmented by xanthopterin (X). The additional material formed behaves like pteroylglutamic acid (PGA), added PGA disappears but little, if at all. Homogenate from PGA-deficient rats is unaffected by X. The PGA content of pig liver homogenate also is increased by X, in a typical 18-hour incubation, the PGA content (in $\mu\text{gm/gm}$ of liver) rose, at pH 7, from 0.25 to 3.0 (4-hour figures somewhat lower), at pH 4.7, 0.65 without or with X, at pH 7 (4 hours) followed by pH 4.7 (14 hours), the values rose from 1.7 to 18.5. At pH 7, added pteroylhexaglutamylglutamate (PG_7) is partially converted to PGA, at pH 4.7 nearly completely, the conversion is unaffected by X. Apparently, the 'potential PGA' of pig liver is resistant,

at pH 4.7, to enzymic conversion to PGA, however, at pH 7 this form is converted enzymatically to a compound, presumably PG_7 , that is susceptible to enzymic conversion to PGA, particularly at pH 4.7. Conceivably, the precursor of PG_7 , at pH 7, is subjected to two reactions, a slower one leading to formation of PG_7 , the other rapidly yielding an inactive substance, X may inhibit this second reaction. Although X also may serve as a precursor, of PGA (through synthesis of PG_7 or its precursor), there is now but little evidence for this (no augmentation by reduced DPN, ATP, p-aminobenzoyleglutamate or its N-formyl derivative). Experiments with isotopically labeled compounds will be described.

Pharmacology of a new cholinergic agent W CLARKE WESCOE (by invitation) and WALTER F RIKER *Dept of Pharmacology, Cornell Univ Medical College, New York City* The compound, 3-acetoxy phenoxy trimethylammonium methylsulphate (Nu 2017, Hoffmann-LaRoche, Inc.), is of considerable pharmacologic and academic interest because of its close chemical relationship to acetylcholine and neostigmine. It possesses both nicotinic and muscarinic properties, injected into the intact cat it produces all the characteristic signs of acetylcholine action. Compared with acetylcholine its duration of action is longer, though still brief, and its potency is less. Like acetylcholine it is inactivated rapidly by the specific and non-specific cholinesterases of erythrocytes, brain, and serum, its affinity for the specific type esterase is lower than that of acetylcholine. It possesses the immediate and intense effects of neostigmine on skeletal muscle, providing thereby additional evidence for the direct action of neostigmine on this effector.

Pentobarbital tolerance in rabbits B A WESTFALL (introduced by J K W FERGUSON) *Dept of Physiology and Pharmacology, Medical School, Univ of Missouri, Columbia, Mo* Seventeen young albino rabbits (mean weight 2.31 kg), selected from a pool of several litters were injected intravenously with an anesthetic dose of pentobarbital sodium (40 mg/kg), and the sleeping-time noted for each animal. One week later the same 17 animals were injected with the same dose of pentobarbital sodium (40 mg/kg), the sleeping-time noted, and this routine was continued at weekly intervals until a total of five injections had been given. The data reveal a significant difference (about 30%) between the mean sleeping-time (121.1 min) after the initial dose as compared to the mean sleeping time (88.6 min) of the same animals after the same dose of pentobarbital one week later. However, the latter value (mean, 88.6 min) was almost identical with the mean sleeping time values observed after the third (mean, 87.7 min), fourth (mean, 87.6 min) and fifth (87.9 min) injections.

of pentobarbital. It might be pointed out that this study is the first reported in which the repeated injections of pentobarbital were as infrequent as one week apart and that the tolerance developed as a result of the initial dose, not only persisted at least a week, but was maintained by weekly injections of the pentobarbital.

Potentialization by means of CO₂ of the action of penicillin against pneumococcus infection. RICHARD W. WHITEHEAD, J. HOWARD WILLIAMSON (by invitation), WILLIAM E. CLAPPER (by invitation), JOSEPH N. SPENCER (by invitation) and WILLIAM B. DRAPER. *Depts. of Physiology and Pharmacology, and Bacteriology, Univ. of Colorado Medical Center, Denver, Colo.* *In vitro* experiments have shown penicillin to be most effective as an antibiotic in an acid medium. It was thought to be of interest to determine the action *in vivo* of induced carbon dioxide acidosis upon the effectiveness of penicillin using white mice as experimental animals. Type III pneumococcus was used as the test organism. One thousand lethal doses were given as the standard quantity for a 20-gm mouse. Preliminary studies showed that the maximum protection with a single dose of penicillin was obtained with 2500 U. Acidosis was induced and maintained for 45 minutes by inhalation of 20% CO₂. In control experiments it was shown that CO₂ alone had no effect upon the time of death of the animals infected with pneumococci. A series of 9 experiments was performed using a total of 72 animals, all of which were given 2500 U of potassium penicillin G at the time of inoculation. Thirty-six of these animals were treated for 45 minutes with CO₂ 2 hours after having been inoculated with the test organism and penicillin. The average life span for the animals treated with penicillin alone was 38.9 hours. The average survival time for the animals given penicillin and carbon dioxide was 47.1 hours. The difference of 8.2 hours in survival time was shown to be statistically significant.

Biopsy technic and analysis of variance applied to pentobarbital inhibition of brain oxidations. D. S. WILKINS (by invitation), R. M. FEATHERSTONE, C. E. GRAY (by invitation), J. T. SCHWIDDE (by invitation), and M. BROTMAN (by invitation). *Divisions of Anesthesiology and Neurosurgery, Depts. of Surgery and Pharmacology, College of Medicine, State Univ. of Iowa, Iowa City, Ia.* This experiment combines a method of dog brain biopsy with analysis of variance and standard manometric technic to ascertain a suitable pentobarbital concentration for studying that drug's effect on the oxygen consumption of various brain levels. The method allows dog brain tissue to be its own control in either *in vitro* or *in vivo* experiments upon drug effects. The dog's calvarium is removed under general anesthesia. Six days later the brain is

biopsied, using procaine in the scalp wound, and tissue slices uninfluenced by drugs are prepared. An attempt is here made to establish a pentobarbital concentration which significantly depresses cortical oxidations without completely inhibiting them. Cortex from each of 5 dogs was treated with 1) 0.00, 2) 0.04, 3) 0.08 and 4) 0.12% pentobarbital. Glucose was added at 90 minutes. Small sample statistical analysis of variance (Snedecor, *Statistical Methods*, 1946) was applied. Main variations were dogs, treatments, time.

Variation Source	Degrees of Freedom	F	Significant at 1% Level
Dogs	4	2.916	4.37
R _x (1) and (2)	1	68.681	8.02
(2) and (3)	1	11.849	8.02
(3) and (4)	1	0.000	8.02

(Error term: first order interaction, making summary applicable to general dog population)

CO ₂ d.w.	(1)	(2)	(3)	(4)
60-90 min	0.183	0.072	0.024	0.029
120-180 min	0.141	0.046	0.021	0.021

Pentobarbital 0.04% appears more satisfactory for the continuance of this study than 0.12% (Quastel) or 0.08% which gave essentially complete inhibition.

Immediate reactions of mice to large amounts of ouabain. W. LANE WILLIAMS and ROBERT TARAIL (introduced by R. N. BIETER). *Depts. of Anatomy and Medicine, Univ. of Minnesota, Minneapolis, Minn.* Mice (20-25 gm) tolerate as much as 2 mg of ouabain (subcutaneous or intraperitoneal) provided the glycoside is administered in several unit amounts of not more than 0.25 mg during an interval of 30-60 minutes. Such daily treatment can be continued for a considerable period (*Federation Proc.* 7:259, 1948). Mice thus treated eventually showed punctate myocardial necrosis and renal and hepatic lesions. Mice also tolerated simultaneous treatment with relatively large amounts of ouabain and calcium provided the total dose for the interval did not exceed that mentioned above. However, a majority of mice receiving a single injection of more than 0.4 mg of ouabain died within 15 to 28 minutes and showed massive pulmonary edema and hemorrhage. Pulmonary involvement was more extensive than that observed terminally in mice treated chronically with similar amounts of ouabain but in divided doses. Some of these mice received as much as 2 cc of saline as solvent or vehicle for the glycoside (Lilly preparation of *Strophanthus gratus*). Equivalent amounts of saline were well tolerated in daily single unit injections for 30 days. The lesions indicate that the acute effects of large amounts of ouabain are directly or indirectly pulmonary. Upon relatively long-term treatment

similar amounts (as to total daily dose) administered as several injections during 30-60 minutes usually produced myocardial damage without concomitant immediately lethal pulmonary lesions

Respiratory activity in vitro of cardiac muscle of ouabainized dogs ALBERT WOLLENBERGER (introduced by OTTO KRAYER) *Dept of Pharmacology, Harvard Medical School, Boston, Mass* The cardiac glycoside ouabain was administered to dogs by slow continuous intravenous infusion. The heart was excised at the onset of cardiac irregularities or of ventricular fibrillation. Slices of left ventricular muscle were prepared and incubated in glucose-phosphate-saline. During the first 30-60 minutes these slices respired at a somewhat higher rate than cardiac slices of control dogs. Subsequently, however, the respiratory rate declined well below the control level, particularly in the case of the slices of fibrillating hearts. Extent and rapidity of the decline were inversely proportional to the tissue concentration. At a tissue concentration of 1% or less, the slices of fibrillating hearts ceased to respire during the second hour of incubation.

Toxicity of hydroquinone for laboratory animals GEOFFREY WOODARD, E CONWAY HAGAN, and JACK L RADOMSKI (introduced by BERT J Vos) *Division of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D C* Because of the interest in the proposed use of hydroquinone as an antioxidant for edible fats, experiments were undertaken to determine its toxicological properties as well as those of its oxidation products quinhydrone and quinone. Approximate acute oral LD₅₀'s in mg/kg of hydroquinone in 2% aqueous solutions are: rats, 320, mice, 400, guinea pigs, 550, pigeons, 300, cats, 70, dogs, 200, and in rats for quinhydrone, 225, and quinone, 130. The approximate intravenous LD₅₀'s in rats are: hydroquinone, 115, quinhydrone, 35, and quinone, 25. The acute toxicity of hydroquinone is reduced in the non-fasted rat and is influenced by the concentration administered. Symptoms of hydroquinone poisoning develop 30

to 90 minutes after oral administration and consist of hyperexcitability, tremors, convulsions and, in addition, salivation in dogs and cats, emesis in dogs and pigeons, and incoordination of the hind limbs of dogs. Deaths occur within a few hours. Quinhydrone and quinone, however, do not produce the same symptoms of poisoning and deaths may be delayed several days. Oral administration of hydroquinone at 100 mg/kg in the dog and at 70 mg/kg in the cat produces mild to severe swelling of the area around the eye, of the nictitating membrane, and of the upper lip. However, dogs receiving 25 and 50 mg/kg daily for 4 months have shown only slight eye involvement. Routine blood counts in cats and dogs acutely and subacutely poisoned with hydroquinone indicate increased activity of the cell-forming tissues.

Evaluation of drugs possessing anti-dysmenorrhoea properties R A WOODBURY and PAUL P C FENG (by invitation) *Division of Pharmacology, Univ of Tennessee, Memphis, Tenn* Vasopressin (0.05 to 0.3 vasopressor units of Pitressin) injected intravenously in humans immediately caused marked uterine activity and caused or intensified the distress characteristically like that of dysmenorrhoea (*Federation Proc* 5: 215, 1946). These observations suggest the hypothesis that drugs which are effective in relieving dysmenorrhoea symptoms by mechanisms other than through analgesia may well possess anti-vasopressin activity to one or more of the actions of vasopressin. Drugs useful in the treatment of dysmenorrhoea such as atropine, papaverine, Pava-trine, Trasentin, Nethamine, Isopropylphenephine, neostigmine, progesterone, testosterone and magnesium salts are found to have pronounced anti-vasopressin activity to one or more of its actions. In the search for additional therapeutic agents for the treatment of dysmenorrhoea, the above data indicate that the anti-vasopressin activity of compounds should be determined along with the anti-histaminic and the anti-cholinergic activity.

THE AMERICAN SOCIETY FOR EXPERIMENTAL PATHOLOGY

Thirty-fourth Annual Meeting

DETROIT, MICHIGAN, April 18-22, 1949

(For possible corrections in any of the following abstracts see the June issue)

Blood pressure measurements and changes in peripheral vascular bed of unanesthetized mice

GLENN H. ALGIRE *National Cancer Inst., Bethesda, Md.* The transparent chamber technique as adapted to a skin flap in mice makes accessible for microscopic observation a layer of subcutaneous and muscular tissue approximately 0.5 mm thick, and having a surface area of 150 sq. mm. Microscopic observations, photographs and quantitative measurements may be made at magnifications up to 500X. An indirect method has been devised for blood pressure measurements of any vascular component within the chamber during direct microscopic examination by transmitted light. Measurements may be made on the same vessel intermittently throughout the day, and repeatedly for the duration of the preparation (approx. 30 days). The apparatus consists of a mercury sphygmomanometer system and air reservoir connected to a glass tube having a thin rubber membrane across the end. A micromanipulator is used to bring the membrane into contact with the under surface of the skin. Pressure applied using the sphygmomanometer bulb results in slight bulging of the membrane. As the entire field is visualized under the microscope one can obtain arterial systolic and diastolic pressure, and venous pressure. The pulse wave can be seen at maximum amplitude approximately midway between systolic and diastolic pressures. Parallel observations and measurements may be made of correlated vascular phenomena such as changes in caliber of vessels, rates of flow, vasomotion, and intravascular agglutination.

Radiation effects on tissues studied with C^{14} -labeled glycine KURT I. ALTMAN, GEORGE W. CASARETT, THOMAS R. NOONAN and KURT SALOMON (introduced by F. S. ROBSCHT-ROBBINS) *Dept. of Radiation Biology, Univ. of Rochester, Rochester, N. Y.* Young adult male rats were exposed to 300 or 600 R total-body Roentgen radiation. Glycine labeled with C^{14} in the α -carbon atom (specific activity of 1.83 μ c/mg) was administered by stomach tube or intravenously at varying intervals after irradiation. The most striking feature observed in rats given 2 μ c by stomach tube immediately after irradiation and killed 24 hours later was the high C^{14} -activity of the gastrointestinal tract contents. With a dose of 300 R 16.7% and with

600 R 32.8% of the total activity administered were found in the gastrointestinal tract contents, as compared with 0.82% in the control animal. In order to eliminate possible malabsorption, glycine (1 μ c) was injected intravenously and rats were sacrificed 5 hours later. It was found that the uptake of labeled glycine by muscle was definitely lowered in all irradiated rats, particularly when glycine was given immediately after irradiation. Definite changes were also observed in brain when glycine was injected 48 hours after irradiation. In this case the total C^{14} -activity of the brain was approximately 3 times that of the control. This increase was due to an increase in the C^{14} -activity of the phospholipid fraction. Radiation effects are also demonstrable in other organs, such as testes, kidney, and liver. When glycine was injected 48 hours after exposure to X-rays a striking increase in the C^{14} activity of the expired CO_2 was observed.

Ovarian hormones and uterine pigmentation in vitamin E-deficiency W. B. ATKINSON (by invitation), H. KAUNITZ and C. A. SLANETZ (by invitation) *Depts. of Anatomy, Pathology and Animal Care, College of Physicians and Surgeons, Columbia Univ., New York City.* One of the most constant findings in intact vitamin E-deficient rats is a chocolate brown discoloration of the uterus which is characterized histologically by the accumulation of acid-fast pigment granules in the cells of the myometrium and, to a lesser extent, the endometrial stroma. The role of the ovary in the development of this condition has not been elucidated. In the present experiments, rats were ovariectomized at 21 days of age and were maintained on a vitamin E-deficient diet which contained 10% commercial lard and which limited the tocopherol intake to about 30 micrograms daily. The animals were divided into 4 groups, the first receiving no further treatment, the remaining 3 being injected once weekly with 5 micrograms of estradiol (Roche-Organon), 4 mg of progesterone (Ciba) or both hormones together, respectively. The uteri were examined macroscopically and histologically after 5 to 11 months. Pigmentation was almost completely absent in the untreated ovariectomized animals. The animals receiving estrogen alone showed slight uterine pigmentation.

in the areas characteristic of the unspayed deficient rat. Concurrent treatment with progesterone seemed to intensify the response. Treatment with progesterone alone evoked slight pigment deposition limited almost entirely to the circular layer of the myometrium. These observations clearly demonstrate that the ovarian hormones are involved in the accumulation of pigment in the uterus of the vitamin E-deficient rat.

Electron microscope studies on virus-cell relationships F B BANG and G O GEY *Depts of Medicine and Surgery, Johns Hopkins Medical School, Baltimore, Md*. Newcastle and mumps viruses freshly prepared from allantoic fluid and saline show characteristic morphologies in the electron microscope. The shape of Newcastle virus when fixed by osmic acid is determined by the concentration of saline in which the virus is fixed. The absorption of both of these viruses on the ghosts of chicken red cells may be demonstrated by fixation with osmic acid in solution at intervals after exposure of the red cell ghosts to the virus, and drying the mixture on formvar screens. The effect of Newcastle virus on chick fibroblasts and macrophages and on rat fibroblasts has been studied by infecting the cells either in roller tube cultures before transfer to formvar coated coverslip preparations or at the time of transfer. A similar morphological effect has been demonstrated on all 3 cell types.

Cytochrome oxidase, succinoxidase and phosphatase activities of tissue of rats on protein-deficient diets E P BENDITT, C H STEFFEE (by invitation), T HILL (by invitation) and T L JOHNSTON (by invitation) *Dept of Pathology, Univ of Chicago, Chicago, Ill*. Protein-deficient but otherwise adequate diets when fed to animals result in loss of protein from many vital organs including the liver and kidneys. In an effort to elucidate the nature of this protein loss rats were sacrificed after varying periods on protein deficient diets. Cytochrome oxidase, succinoxidase and alkaline phosphatase were assayed in liver homogenates and alkaline phosphatase determined in kidney homogenates. Cytochrome oxidase and succinoxidase decreased progressively with time and somewhat faster than the liver protein. Liver phosphatase, on the other hand, increased in concentration as the liver shrank. The total liver phosphatase remained approximately constant. Kidney phosphatase after several months of protein depletion was reduced in proportion to the kidney protein. The difference in behavior of the liver phosphatase from the kidney enzyme and from the other liver enzymes studied is apparently related to the fact that the liver enzyme is not present to a significant extent in the hepatic parenchymal cells but is associated with the vascular bed and bile ducts. This work substantiates that

of others who assayed under similar conditions other enzymes including catalase, xanthine dehydrogenase, cathepsin and arginase (Miller, *Fed Proc* 7 174, 1948) d-amino acid oxidase (Seifter et al *Fed Proc* 7 187, 1948). It appears from the evidence that at least a part of the 'reserve' protein lost from vital organs such as the liver and kidney by animals on protein deficient diets is not inert material but is part of the actively functioning cytoplasmic protein constituents, i.e. enzymes.

Effect of acute x-radiation on distribution and excretion of radio sodium in the rat L R BENNETT, VERA C BENNETT and JOE W HOWLAND (introduced by F S Robschert-ROBBINS) *Dept of Radiation Biology, Univ of Rochester School of Medicine and Dentistry, Rochester, N Y*. Radiated rats have been shown to have an increased thiocyanate space for 2 weeks following a mid-lethal dose of x-radiation. A study of the sodium distribution and excretion of similar animals using radio sodium has been made. In rats during the first 4 days post radiation a marked retention of radio sodium occurs. Tissue distribution studies show a shift into the intestinal tract which may exceed that observed in control animals by as much as 2% of the total dose administered. Smaller shifts of radio sodium into the kidney and spleen are noted. There is an increased radio sodium content in the liver which appears to be definitely related to the increased serum level to which it holds a constant relationship. The serum sodium content increases, the maximum levels (up to 5-8 mEq) being observed at the end of 3-4 days after irradiation. Urinary radio sodium excretion may be reduced to one half that observed in control animals. Studies on dehydrated rats indicate that the urinary retention and elevated blood sodium level are not accounted for on the basis of dehydration alone.

Lipids in the lymph of rats J L BOLLMAN and E V FLOCK *Mayo Foundation, Rochester, Minn*. Lymph from the lymphatic draining the small intestine and lymph from the liver and lymph from the thoracic duct was obtained in different rats after recovery from the operation during which a small plastic tube was inserted into the respective lymphatic and brought through the abdominal wall. The concentration of neutral fat of the intestinal (and thoracic duct) lymph of the fasting rat was considerably greater than that of the plasma. The phospholipid but not the cholesterol content of this lymph was also higher than that of plasma. The feeding of a lipid free meal did not alter these values. Following the feeding of a meal containing fat but devoid of phospholipid or cholesterol there was a marked increase in the neutral fat and phospholipid but not the cholesterol content of the intestinal lymph. The feeding of phospholipid produced only the increase in the phos-

pholipid content of the lymph which would accompany the increased neutral fat (from hydrolyzed phospholipid) content of the lymph. The concentration of neutral fat, phospholipid and cholesterol in lymph from the liver of fasting rats was almost the same as the concentrations of those substances in the plasma and were not materially altered by feeding meals which did elevate the plasma content of these substances.

Blood supply of neoplasms in the liver CHARLES BREEDIS and GANG YOUNG (by invitation) *Dept of Pathology, Medical School, Univ of Pennsylvania, Philadelphia, Penna, and Pathology Research Inst, Medical College, National Sun Yat Sen Univ, Canton, China*. By means of injection experiments during life and after death, it was shown that malignant neoplasms growing in the liver tend to acquire an exclusively arterial blood supply. The neoplasms tested were as follows: V-2 carcinoma strain of rabbits, T-241 sarcoma strain of mice, metastases of spontaneous carcinoma of the kidney of the frog, and primary hepatomas and cholangiomas of rats induced by butter yellow. A variety of metastatic carcinomata found at autopsy in 12 human cases were similarly injected. In all instances the blood supply to the tumors was predominantly or exclusively arterial, in sharp contrast to the predominantly portal supply of liver tissue. It was found that the blood supply of the experimental rabbit tumors was arterial whether inoculations had been made into the portal vein, the hepatic artery or directly into the liver parenchyma. Only very small tumors (1-2 mm or less) tended to retain some portal vessels. With increase in size of the tumors the portal vessels became obliterated, and blood was supplied through the hepatic artery.

Cutaneous melanin production in the mouse by 5, 9, 10-trimethyl, 1-2-benzanthracene F H BURGOYNE, W E HESTON, J L HARTWELL (all by invitation) and H L STEWART *National Cancer Inst, Bethesda, Md*. By painting the skin at the base of the tail of F_1 hybrids of strains $C_{57}B1 \times dba$ twice weekly with 0.06% solution of 5,9,10-Trimethyl, 1-2 Benzanthracene in benzene, localized pigmented areas were produced. The pigmented areas appeared in the skin between the 5th and 15th months, often in association with areas of atrophy, hyperplasia, inflammation, ulceration, papilloma formation, squamous cell carcinoma and sarcoma. In histological preparations the pigment in these areas was blackened by Krajian's silver impregnation method, failed to give a positive Prussian Blue reaction and was bleached by strong oxidizing agents, thus identifying it as melanin. When the pigmented areas were bleached they were found to be composed of melanophores or macrophages with finely stippled cytoplasm and an eccentrically placed nucleus.

The 'dopa' reaction applied to skin recently excised from the painted area revealed large numbers of melanoblasts in the basal layer of the epidermis. Thus, painting the skin of these F_1 hybrid mice with 5,9,10-Trimethyl, 1-2 Benzanthracene resulted in an increase of melanoblasts, with deposition of melanin in macrophages in the derma and the subcutaneous tissue. No malignant melanomas were induced.

Effects of x-rays on the metabolism of nucleic acids in hematopoietic tissues C E CARTER (introduced by SHIELDS WARREN) *Biology Division, Oak Ridge National Lab, Oak Ridge, Tenn*. The alterations in the metabolism and content of nucleic acids in hematopoietic tissues have been studied through microchemical and isotope procedures employing P^{32} following varying doses of total body x-radiation. In bone marrow the desoxyribonucleic acid content falls within the first 24 hours following radiation. Similar changes were found in spleen and thymus where the desoxyribonucleic acid changes are marked but a decrease in ribonucleic acid content is also found. No immediate effects of radiation on the content of nucleic acid in these tissues were noted. Experiments employing P^{32} in bone marrow cell suspensions in homologous serum likewise showed no significant alteration of the rate of incorporation of P^{32} into nucleic acids following removal from rabbits immediately after exposure to 1000 r. Experiments conducted 24 hours following exposure show marked decrease of respiration in 500 r and 1000 r group with elevated ratios of ribonucleic acid to desoxyribonucleic acid specific activity indicating a depression of desoxyribonucleic acid synthesis. Of several enzymes concerned with nucleic acid and protein metabolism studied in spleens of irradiated rats, only ribonuclease shows significant deviation from normal and these changes are established in the first 24 hours following exposure. All of the aforementioned changes pose the problem of correlation of metabolic activity with cell type in a complex cellular system.

Experimental production of a nutritional macrocytic anemia in swine G E CARTWRIGHT (by invitation) and M M WINTROBE *Dept of Medicine, Univ of Utah College of Medicine, Salt Lake City, Utah*. A deficiency of pteroylglutamic acid has been produced in 32 swine fed a basal diet supplemented with sulfasuxidine, a folic acid antagonist (crude methyl folic acid) and all the known B vitamins except pteroylglutamic acid. The hematologic manifestations observed were 1) a severe macrocytic anemia, 2) leukopenia, due to a reduction in both polymorphonuclear and mononuclear cells, and 3) a slight thrombocytopenia. The bone marrows were hyperplastic with a relative increase in immature nucleated red cells. These cells closely resemble the megakaryoblasts seen

in the bone marrow of patients with pernicious anemia in relapse. The hematologic manifestations described above, appeared in the presence of 'extrinsic factor' in the diet and their development was not prevented by the daily intramuscular administration of 1 U S P U of purified liver extract from the beginning of the experiment. The feeding of a diet low in protein (10% casein) resulted in a more rapidly developing anemia but the degree of macrocytosis was less. Pteroylglutamic acid deficient pigs, either receiving 'extrinsic factor' (crude casein) in the diet or an 'extrinsic factor-free' diet (purified casein) responded rapidly and maximally to pteroylglutamic acid, pteroyldiglutamic acid, pteroyltriglutamic acid or to pteroylheptaglutamic acid. Thymine and xanthopterin had little or no activity. Tyrosine, adenine and uracil were inactive. Purified liver extracts as well as vitamin B₁₂ were found to possess some hemopoietic activity under the conditions employed but the activity was considerably less than that of pteroylglutamic acid compounds.

Biochemical and clinical effects of cationic exchange resin. THEODORE S. COBBEY, JR. (by invitation), ROBERT H. WILLIAMS, NORMA MACRAE (by invitation) and BEVERLY T. TOWER (by invitation) *Dept of Medicine, Univ of Washington, Seattle, Wash.* Several cationic exchange resins have been given to normal subjects and patients with edema. Investigations were made for changes in the clinical status and in the balance of H₂O, Na, K, Ca and Mg. The resins markedly increased the excretion in the stools of Na, K, Ca and Mg. Although there tended to be a decrease in the excretion of these elements in the urine, the response was variable. The increased excretion of the elements in the stools was not associated with a comparable decrease in the urine. The resins promoted a marked increase in ammonia and titratable acidity in the urine. In certain patients with edema associated with congestive heart failure it was noted that loss of weight and edema occurred simultaneously with a positive Na balance, conversely, gain in weight and edema occasionally was disproportionate to the quantity of Na retained. These observations suggest that the Na balance need not necessarily parallel the water balance in congestive heart failure. After a period of 3 days on the resin one non-cardiac subject had a marked diuresis followed by weakness, hemoconcentration, and a distaste for water. These symptoms were immediately relieved by intravenous saline. One cardiac patient developed the same picture after being on the resin for 21 days.

Determination of the blood iodine. A simplified method for use in the clinical laboratory. ARTHUR C. CONNOR (by invitation), ROY E. SWENSON (by invitation) and GEORGE M. CURTIS *Dept of Research Surgery, Ohio State Univ, Columbus, Ohio*

A shorter and simpler plan of determining the blood iodine has been attained by developing a method which requires no transfer of material during the entire procedure, and necessitates an apparatus of specially constructed glassware. Three ml of serum are fractionated in a 250 ml reagent flask by use of the Somogyi reagent. This flask is centrifuged in an International, size 2 centrifuge. The supernatant fluid containing the soluble 'inorganic' iodine is poured off and read in the colorimeter directly. The protein precipitate containing the physiologically significant protein-bound iodine remains in the 250 ml reagent flask and is oxidized by the chromic acid procedure. The same flask fits a distillation assembly. The iodine is then released by phosphorous acid and collected directly in a colorimeter tube which also fits the distillation assembly. The quantity of iodine is determined by its catalytic effect on the rate of reaction between ceric sulfate and arsenious acid. An ordinarily well-trained technician can make an analysis in less than 3 hours and about ten analyses in an eight-hour day. The average deviation is plus or minus 5%. Since the method is essentially a closed procedure contamination has been practically eliminated.

Kidney protein associated with systemic arteriolar necrosis. G. I. DESUTO-NAGY and L. L. WATERS (introduced by M. C. WINTERNITZ) *Dept of Pathology, Yale Univ School of Medicine, New Haven, Conn.* Previous experiments have demonstrated that when saline extracts of kidney tissue are injected into nephrectomized dogs, segmental necrotizing lesions of systemic arterioles result (Winternitz, *et al*, 1939). In continuance, acid extracts of fresh hog kidney were subjected to fractional acetone precipitation. The precipitates were redissolved, dialyzed, and reprecipitated with acetone. Three fractions resulting from these procedures have been examined for their vasomotor activity and for their association with the occurrence of acute arteriolar lesions. The dialysates of all the fractions contained vasodepressor substances of small molecular weight. When these were injected into nephrectomized test dogs no systemic vascular changes were encountered. A complex fraction, containing vasopressor (renin-like) substances, thromboplastic material, inert globulins and lipids was found to be associated with the frequent occurrence of vascular changes in the test animals. A small non-dialyzable fraction of the acid extract obtained on precipitation by 20 volumes of acetone was devoid of either vasopressor or vasodepressor activity. This protein-like material contained phosphorus. When injected into nephrectomized dogs it was found to be associated with widespread arteriolar necrosis. In some instances necrosis of arterial smooth muscle followed the injection of as little as 19.1 mg N.

Iron excretion in human subjects as measured by the isotope technique REUBENIA DUBACH (by invitation), CARL V MOORE and SHEILA CALLENDER (by invitation) *Washington Univ School of Medicine, St Louis, Mo* The excretion of iron by human subjects over a 140-day period was studied by the isotope technique. Observations were continued for a period of time greater than the length of life of the red cells into which labeled hemoglobin was incorporated in order that any unusual excretion of radioiron at the time of hemoglobin breakdown might be noted. Following intravenous injections of 5 to 20 mg of radioiron, 4 normal individuals excreted in the feces 0.03 to 0.07% of the dose per day for 4 to 24 days, later, after the isotope had reached a constant level in the blood (75 to 92%), an average of approximately 0.01% of the dose was excreted daily for 140 days. A woman with hypochromic anemia excreted an average of 0.028% of the dose daily for the first 5 days, later, when 100% of the isotope had appeared as hemoglobin, she excreted 0.002 to 0.007% of the dose daily for 140 days. A patient with sickle cell anemia excreted an average of 0.05 to 0.08% of the injected dose per day. Assuming complete mixing of isotopic iron with total hemoglobin iron, the total fecal excretion of iron derived from hemoglobin was calculated to be 0.2 to 0.9 mg/day for the normal subjects, 0.04 to 0.13 mg for the woman with hypochromic anemia, and 1.3 to 1.7 mg for the girl with sickle cell anemia. The effect of a hemolytic crisis on iron excretion was studied in 2 dogs. After a high concentration of radioiron had been built up in the red cells by repeated injections, severe hemolysis was induced with phenylhydrazine. The excretion of iron in the feces and urine increased significantly (0.1 to 0.12% of the dose per day, compared to 0.01 to 0.06% in control periods) but remained small in relation to the amounts of iron liberated by red cell destruction.

Effect of hydrogen-ion concentration on the cultivation of macrophages in vitro I N DUBIN and C K YEN (by invitation) *Division of Pathology and Bacteriology, Univ of Tennessee College of Medicine, Memphis, Tenn* Macrophages from chick embryo spleen were grown in vitro at 37°C for 4 to 6 days using chicken serum and salt mixtures containing bicarbonate buffers as nutrient. The pH values, which ranged from 6.4 to 9.0, were maintained at constant levels by continuous flow of gas-mixtures containing required concentrations of CO₂. The pH values were determined with a Beckman pH meter. The macrophages grew equally well between pH 6.8 to 8.4. Growth fell off sharply at pH 6.6 and ceased about pH 6.4, beyond pH 8.4 growth was poor, but cells in rare numbers were found up to pH 9.0. There was indirect evidence that the internal pH of the cells was affected, as

shown by the color reactions of the cells when stained with Giemsa, on the acid side the cells stained reddish while on the alkaline side bluish. On the acid side the cells were round, large, contained abundant cytoplasm and numerous fat vacuoles, there was also a tendency towards formation of multinucleated giant cells. On the alkaline side the cells had much less cytoplasm and fewer fat vacuoles and presented a stellate or elongated shape. This difference in shape may reflect a difference in irritability and mobility. The mechanism of action of the pH is not known but may operate through changing the concentration of available ions such as calcium and phosphate.

Acid phosphatase activity of the gastric contents of patients with carcinoma of the stomach CHARLES E DUNLAP and GEORGE W CHANGUS (by invitation) *Dept of Pathology, School of Medicine, Tulane Univ and Charity Hospital, New Orleans, La* In patients with carcinoma of the stomach histochemical studies have shown high acid phosphatase activity in the neoplasm and also in the surrounding gastric mucosa. Chemical determinations for acid phosphatase were done by the method of Gutman and Gutman on gastric contents, aspirated from a series of fasting patients with and without carcinoma of the stomach. It was found that aspirates having an initial pH of less than 3.5 seldom contained significant amounts of acid phosphatase and that the enzyme, when present in other samples, could be irreversibly inactivated, in vitro, by acidification to pH 3.5 or less. At a pH greater than 3.5 the enzyme was fairly well preserved for 48 hours at 4°C but rapid deterioration occurred at room temperature. Thus gastric aspirates containing 'free acid' (pH less than 3.5) as well as those that had stood for more than 2 hours without refrigeration were considered unsuitable for acid phosphatase determinations. In a great majority of the patients with carcinoma of the stomach no 'free acid' was present and the aspirates were found to contain more than 10 units of acid phosphatase per hundred cc. Most samples from patients without gastric carcinoma contained less than 10 units. The study, to date, has covered only a limited number and variety of gastric lesions and includes no cases of early carcinoma.

Blood dyscrasia in mice ingesting toluidine blue THELMA B DUNN *National Cancer Institute, Bethesda, Md* Inbred mice were given 0.1% or 0.2% solution of toluidine blue instead of drinking water. With an appropriate concentration of the dye the urine was deeply colored, but no severe toxic symptoms developed. After an interval of 10 days or longer the peripheral blood in some animals showed a reduction in the circulating red blood cells without a corresponding reduction in hemoglobin. In the blood smears the erythrocytes showed fragmentation, polychromasia, anisocytosis.

sis, macrocytosis, siderocytosis and normoblasts. The total and differential leukocyte counts were not significantly altered. On postmortem examination a pronounced siderosis of the spleen, liver, bone marrow, kidney and lymph nodes was found. The bone marrow showed hyperplasia of erythropoietic elements. When the toluidine blue was withdrawn, the peripheral blood picture rapidly returned to normal, and the siderosis of organs decreased. This method is now being used to produce siderosis in the tissues and hyperplasia of the bone marrow in mice. The possible effect on the incidence of neoplastic disease, particularly leukemia, is being investigated.

Incidence of neoplasms and pathological changes in rats as a result of prolonged choline deficiency CYRUS C. ERICKSON and WALTER GOEBBEL (by invitation) *Depts of Pathology and Surgery, Duke Medical School, Durham, N. C.* Neoplasms of one or more types were observed in 58% of choline-deficient rats by Copeland and Salmon (D. H. Copeland and W. P. Salmon, *Am J Path* 22: 1059, 1946). The purpose of these experiments was to test a similar choline-deficient diet for the production of neoplasms in the Osborne-Mendel strain of rats used in this laboratory, and to utilize such test animals for anterior chamber tumor transplant experiments. The diet consisted of 30% alcohol-extracted peanut meal, 6% alcohol-extracted casein, 40% sucrose, 20% pure lard, and 4% salt mixture. To each kg of diet, vitamins were added as in the Copeland-Salmon choline-deficient diet. The experimental diet was started on 149 rats at the age of 20-30 days and was given ad libitum. Choline supplement was administered to the choline-deficient group during the first 4 weeks. Twenty-four rats making up the control group received the same diet with 3 gms of choline chloride added to each kg of diet for the duration of the experiment. Sixty of the experimental group and 20 of the control animals were still living after 19 months. Cirrhosis of the liver was a consistent finding in the rats on the deficient diet. The high incidence of neoplasms previously reported as a result of this choline-deficient diet has not been observed in this experiment in the 65 choline-deficient animals expiring prior to 19 months.

Injury and recovery of mouse testes following whole-body exposure to x-radiation ALLEN ESCHENBRENNER, *National Cancer Institute, Bethesda, Md.* Groups of mice received 50 R, 100 R, 200 R, 300 R, or 400 R acute whole-body radiation at 3 months of age. Four mice of each dose group and four non-irradiated mice of the same age were killed at weekly intervals up to and including 12 weeks following exposure. The testes were dissected free and weighed on a torsion balance after which they were prepared for histologic examination. Minimum testes weights were observed from

3-4 weeks after irradiation and returned to normal 6 to 14 weeks after irradiation. The minimum weights of testes observed were dependent upon dose. The time required to effect the minimum weights as well as the time required for the weights to return to normal were functions of dose. Histologic examination of these testes indicates that the decrease of testes weights following acute irradiation is due to marked transient retardation in rate of production of spermatogonia. The progeny of spermatogonia are not appreciably destroyed nor prevented from maturation. After it was found that the weight of testes of mice exposed to 200 R had returned to normal by 12 weeks, an additional group of mice was given a whole-body exposure of 200 R at 3 months of age and again 12 weeks later. Following the second exposure the mice were killed and examined as before. The pattern of injury and recovery following the second dose, as reflected in fresh testes weights, was the same as observed following a single dose. These experiments on acute irradiation confirm conclusions drawn from earlier experiments on chronic irradiation, that the primary effect of radiation of the testes is on the spermatogonia.

Massive hepatic necrosis in protein-depleted, partially hepatectomized rats fed hypertonic diets ROBERT L. ESTRADA (by invitation), ZACHARY A. SIMPSON (by invitation), HARRY M. VARS and I. S. RAYDIN *Harrison Department of Surgical Research, Schools of Medicine, Univ of Pennsylvania, Philadelphia, Penna.* The effect of forced feeding with concentrated solutions of sucrose, gelatin and casein hydrolysate on normal partially hepatectomized and on protein-depleted, laparotomized or partially hepatectomized rats has been studied. Massive hepatic necrosis occurred in the rats receiving these diets. Gastric distention and increased intra-abdominal pressure were observed in the experimental groups and were simulated in others by attaching a balloon to the stomach at laparotomy. Pneumoperitoneum immediately after laparotomy demonstrated that increased intra-abdominal pressure per se was not sufficient to produce liver injury. The emptying time of the stomach following the administration of the various diets was determined by x-ray examination. No retention was present after 2 hours in the control group. In the groups receiving 50% sucrose and the 50% hydrolyzed casein diet, there was 50% and 90% gastric retention, respectively, at the end of 2 hours. The debilitated rat is very susceptible to liver injury. It is our opinion that the hepatic necrosis which occurred in rats receiving the 50% casein hydrolysate diet was not due to toxicity of the amino acids, since similar lesions were produced when other diets were fed, and that gastric distention per se was sufficient to slow the portal circulation and to lead to anoxia of the hepatic

parenchymal cells. The condition was further aggravated by pressure exerted directly upon the liver. This represents another mechanism which by interfering with hepatic blood supply leads to hepatic necrosis, the extent of the necrosis being further aggravated by the nutritional state of the animals.

Effect of lecithin in the formation of thrombin
JOSEPH E. FLYNN and EUGENE T. STANDLEY, (introduced by H. P. SMITH) *Dept. of Pathology, Columbia Univ., New York City*. In activating purified prothrombin, the amount of thrombin obtained depends in part upon the amount of Factor V added. With a suboptimal amount of Factor V, the yield of thrombin is low, and can be increased by the addition of lecithin. The lecithin is not identical with Factor V, but it does potentiate its effect.

Inorganic composition and phosphatase activity of human cartilage in relation to morphological differentiation
RICHARD H. FOLLIS, JR. *Dept. of Pathology, Johns Hopkins University, Baltimore, Md.* A method has been devised to compare the chemical composition and morphological characteristics of developing human cartilage. Segments of whole costochondral junctions removed at autopsy from children of varying ages are clamped in a freezing-type microtome by the shaft and first sliced longitudinally down through the cartilage just into the shaft. Transverse slices of desired thickness then are made completely through one of the two longitudinal halves and part-way through the other. Appropriate chemical analyses are made of the free slices, their fellow halves, held together by an intact outer layer of cartilage, are fixed and prepared for histological examination. This technique permits a comparison of chemical composition and cellular differentiation in various strata of developing cartilage, a unique tissue with such adaptability to studies of chemical embryology. Observations to be presented include the percentage composition of calcium, phosphorus and carbonate and phosphatase activity, all in direct relation to the degree of maturation of cartilage cell strata, from those containing small undifferentiated cells to those having large hypertrophic cells being invaded by capillaries. There is a characteristic quantitative increase in concentration of the inorganic elements which proceeds slowly and then suddenly mounts rapidly as the zone of hypertrophic cells is reached. Similar, though more marked differences, are found in phosphatase activity.

Nucleic acids and the production of antibody by plasma cells
CAROLYN FORMAN (by invitation), WILLIAM E. EHRLICH and DAVID L. DRABKIN *Depts. of Pathology and Biochemistry, Graduate School of Medicine, Univ. of Pennsylvania, and the Philadelphia General Hospital, Philadelphia,*

Pa. It has been suggested that protein synthesis is associated with nucleic acid metabolism. Deoxyribose nucleic acid (DNA) appears to be connected with the multiplication of chromosomes, whereas the production of cytoplasmic protein is thought to be conditioned by ribose nucleic acid (PNA). We have investigated the relationship of antibody formation and the production of nucleic acids in lymph nodes of rabbits, injected with typhoid vaccine. The increase in DNA was found to be parallel with the increase in weight of the nodes, suggesting that the latter was due largely to multiplication of cells. PNA, on the other hand, showed its greatest rise between the 4th and 6th day after vaccine injection when antibody formation is at the peak. Thereafter, PNA rapidly decreased. A histologic study of methyl green and pyronin stained sections of the nodes revealed that during the first 6 days of the experiment the cellular reaction was chiefly that of plasma cell proliferation, and that the plasma cells contained most of the PNA. The lymphocytes, on the other hand, showed their greatest activity only after PNA and antibody formation had passed their peaks. These results are interpreted as indicating that the plasma cell and not the lymphocyte is responsible for antibody formation.

Minimum daily requirements of indispensable amino acids for maintenance of adult rats
L. E. FRAZIER, R. L. WOOLRIDGE, C. H. STEFFEE, (all by invitation) and E. P. BENDITT *Dept. of Pathology, Univ. of Chicago, Chicago, Ill.* The quantitative requirements for the 9 amino acids indispensable for maintenance of appetite, weight and nitrogen equilibrium of adult, well-nourished, male, albino rats (Wissler *et al.* *J. Nutrition* 36:245, 1948) were measured. Mixtures of crystalline amino acids were used as the nitrogen source. The caloric intake was maintained at or slightly above 1200 Cal/m²/day and the nitrogen intake at or slightly above 5 gm/m²/day. Vitamin, mineral and fat intakes were adequate. The level of the amino acid under consideration was varied while other diet factors were kept constant. Weight changes and nitrogen balance were determined. Seven to 14 animals were used for each amino acid. The minimum quantity of amino acid necessary to maintain weight and nitrogen equilibrium was estimated from the curves relating amino acid intake and weight change or nitrogen equilibrium respectively. In all instances the quantity of amino acid necessary to maintain nitrogen equilibrium appeared to be somewhat lower than the amount necessary to maintain the weight. The requirements for each amino acid for nitrogen equilibrium and weight balance respectively were as follows: Tryptophane 1.8 and 2.2, histidine 2.1 and 2.2, phenylalanine 3.1 and 6.0, lysine 3.7 and 4.5, threonine 5.1 and 5.3, methionine 5.3 and 7.3, leucine

6.5 and 8.0, valine 7.0 and 10.0, isoleucine 10.8 and 13.7 mgm/100 cm² of body area/day. Furthermore, animals offered an amino acid mixture containing all the indispensable amino acids at the above levels were maintained in nitrogen equilibrium.

Fates of parenterally administered homologous serum protein and casein hydrolysate JOHN FULLER (by invitation), E. M. HUMPHREYS (by invitation), C. H. STEFFEE (by invitation), R. W. WISSELER (by invitation), and E. P. BENDITT *Dept of Pathology, Univ of Chicago, Chicago, Ill.* Groups of protein-depleted rats were fed a protein-free basal ration by gavage. One group was given homologous serum intravenously, a second, casein hydrolysate (Amigen) intravenously, and a third, Amigen orally. Each animal received 5 gms protein/kgm body wt/day for 9 days. Nitrogen balance, blood compartments, and extracellular fluid volume determinations were made. Carcasses, and livers were analyzed for protein, fat, water and ash. Percentages of nitrogen intake retained in 9 days were

Compartment	I V serum	I V hydrolysate	Oral hydrolysate
Plasma	6.9	2.6	1.1
Liver	8.9	4.9	4.6
Carcass	32.8	10.7	36.8
Total	48.6	18.2	42.8

Animals receiving oral hydrolysate had the smallest extra- and intra-cellular fluid and plasma volume increases. The largest plasma volume as well as plasma protein increases were associated with intravenous administration of serum. Although the animals receiving intravenous hydrolysate gained far less plasma protein than those receiving serum, their plasma volume increases were nearly as great. No increased nitrogen excretion was found in the serum-injected animals in the ten days following cessation of injection during which they received an adequate protein diet. It appears that these rats utilized injected serum protein for tissue synthesis. The rats appeared to utilize the serum protein more than twice as effectively as the injected casein hydrolysate. The poorer utilization of the injected hydrolysate may have been due to its content of polypeptides.

Prophylaxis of allergic acute disseminated encephalomyelitis in guinea pigs with salicylate and para-aminobenzoic acid ROBERT A. GOOD, BERRY CAMPBELL and T. A. GOOD (introduced by IRVINE McQUARRIE) *Univ of Minnesota, Minneapolis, Minn.* That acute diffuse central nervous system disease can be produced in experimental animals by injection of heterologous and homologous brain tissues was shown by Rivers, Sprunt, and Berry. Schwentker and Rivers, among others, demonstrated that this phenomenon was associated

with formation of organ-specific antibodies against brain tissue. Recent studies have resulted in the production of auto-allergic disease of the central nervous system of monkeys, rabbits, and guinea pigs by a single or few injections of homologous brain tissue with adjuvants. Recent studies have shown that 70 to 90% of guinea pigs develop symptoms of progressive encephalomyelitis 13 to 37 days after injection of homologous brain plus an adjuvant of heat killed acid fast organisms, Falba, and Bayol F. In an attempt to test the effect of para-aminobenzoic acid and sodium salicylate medication on the course of this disease, 124 guinea pigs were studied. Ninety % of control animals developed progressive encephalomyelitis between 13 and 20 days after a single injection of guinea pig brain with adjuvants. While neither subcutaneous administration of sodium salicylate nor oral administration of para-aminobenzoic acid in moderate dosages alone affected the course of the allergic encephalomyelitis, premedication and medication with a combination of salicylates and para-aminobenzoic acid reduced its incidence to 10%. Administration of sodium salicylate in larger dosages resulted in demonstrable but less effective protection in spite of salicylate toxicity. Neither agent alone nor combination of the two had any ameliorating effect when administered after the encephalomyelitis had developed.

Canine hemophilia the clotting anomaly and effectiveness of transfusions JOHN B. GRAHAM (by invitation), JOSEPH A. BUCKWALTER (by invitation), L. J. HARTLEY (by invitation) and K. M. BRINKHOUS *Dept of Pathology, Univ of North Carolina, Chapel Hill, N. C.* A sex-linked hemorrhagic disease of male dogs was described by Field et al. These animals have been studied in our laboratory for the past two years. The clotting defect appears to be identical with human hemophilia. Bleeding time from small puncture wounds is normal while bleeding from larger wounds is extensive. The clotting time is prolonged. Prothrombin is present in normal amounts, but its conversion to thrombin is extremely slow. The rate of prothrombin utilization can be increased by the addition *in vitro* of thromboplastin, normal dog plasma, or Fraction I (Armour, Squibb). Prothrombin conversion in whole hemophilic blood approximates the normal rate after addition of normal plasma. This corrective action appears to be dependent upon the presence of formed elements, particularly platelets. Mixtures of platelet-poor hemophilic plasma and platelet-poor normal plasma do not clot for hours, and almost no prothrombin is converted to thrombin. Normal blood and plasma transfusions correct the clotting defect. The corrective effect is most pronounced for approximately 24 hours, but a slight effect persists as long as 72-120 hours. Normal serum trans-

fusions have no effect Transfusions of fresh and aged hemophilic blood do not alter the clotting anomaly Untreated bleeder dogs usually die by the age of 3 months By the use of repeated plasma transfusions, the hemophilic dogs have been reared to maturity

Spontaneous adenomatous gastritis of mice of strain dba WILLIAM V HARE (by invitation) and HAROLD L STEWART *National Cancer Institute, Bethesda, Md* Inbred mice of strain dba develop a spontaneous lesion of the glandular stomach and duodenum, which is progressive and may be fatal Grossly it is characterized by a pebbled appearance of the gastric mucosa or by large hypertrophic rugae with deep furrows between them, or a combination of the two Microscopically the epithelial cells are frequently hyperchromatic and the glands are atypical and may penetrate the submucosa The submucosa usually shows an inflammatory reaction which may also be present in the forestomach as well In the duodenum single or multiple papillary adenomas develop having a broad base, and tending to fill the lumen, although they do not invade the muscularis No evidence of malignant degeneration in either the gastric or duodenal lesions has been found In some cases, however, there is obstruction of the pyloric canal

Effect of aging on the protein fractions of the normal human heart JOHN W HARMAN and JEAN H WEBSTER (introduced by D MURRAY ANGEVINE) *Dept of Pathology, Univ of Wisconsin Medical School, Madison, Wis* A series of 34 human hearts, of ages varying from birth to 80 years and normal as determined by gross and histological features, are analyzed for various protein fractions Representative samples of the principal chambers are ground finely, acetone dried and defatted with Skelly Solvent #2 Aliquots dried to constant weight are analyzed for total protein, alkali soluble protein, collagen and elastin by Conway's micro-kjeldahl technique At different ages the ventricles are unaltered in the proportions of these fractions Up to the age of 10 the 4 chambers are chemically similar, whereas beyond this age in certain hearts the atria contain a significantly increased quantity of collagen Differences between atria of the same organ are not observed, these chambers fluctuate concomitantly in their composition In all chambers, with the usual conversion factor of 6.25, only about 75-80% of the standard dried preparation is composed of protein Part of the remaining per cent is a fraction soluble in 30% KOH, precipitable with alcohol, which is Biuret negative and yields no reducing substances by acid hydrolysis The constant proportion of the protein fractions in aging normal hearts, except for certain atria, indicates that senility does not quantitatively affect the organ Collagenization of the atria may be of significance functionally, since

these chambers so frequently suffer rhythmic disorders

Nitrogen mustards as effective blood and plasma sterilizing agents FRANK W HARTMAN and GEORGE H MANGUN (by invitation) *Dept of Labys, Ford Hospital, Detroit, Mich* The authors recently demonstrated the ability of methyl-bis(beta-chloroethyl) amine hydrochloride (HN2) to sterilize blood and plasma with relatively slight changes in their components with the exception of an increase in prothrombin time Other mustards (tris(beta-chloroethyl)amine and bis(beta-chloroethyl) sulfide) are approximately equal in effectiveness The virucidal and bactericidal action of HN2 is dependent to some degree upon the medium, the pH, and the presence of substances competing for the agent In citrated plasma the sterilizing dosages of HN2 are 1) New Jersey vesicular stomatitis, 300 mg/l, 2) lymphocytic choriomeningitis, 400 mg/l, 3) St Louis encephalitis, 300 mg/l, 4) *E coli*, 450 mg/l, 5) Hemolytic streptococcus, 450 mg/l, 6) *Staphylococcus aureus*, 800 mg/l, 7) *Bacillus subtilis*, 150 mg/l In the absence of plasma HN2 is still more effective, illustrating the protective or competitive effect of the plasma In saline, *E coli*, for example, is completely killed at 100 mg/l In ACD citrated whole blood, 450 mg/l are required for the complete destruction of N J vesicular stomatitis virus Studies carried out on ACD citrated whole blood treated with 500 mg/l of HN2 show 1) a very slight increase in fragility to hypotonic saline, 2) no immediate hemolysis nor increase above control hemolysis on prolonged storage, 3) a normal rate of loss of potassium from the red blood cells

Renal excretion of phosphate in the dog, influence of potassium, action of parathyroid extract C A M HOGGEN (by invitation) and J L BOLLMAN *Mayo Foundation, Rochester, Minn* The existence of a maximal tubular reabsorption of phosphate was confirmed utilizing plasma ultrafiltrates for the measurement of plasma inorganic phosphate During the course of a 6-8 hour experiment, the maximum will decline 25-50% Incorporation of potassium in the infusion fluid would, under certain conditions, restore the maximum The action of intravenous parathyroid extract was measured on the tubular reabsorption of endogenous phosphate in the intact dog for 2 hours after administration A slight rise in plasma phosphate and urinary excretion of phosphate resulted No evidence was obtained to support the hypothesis that parathyroid extract inhibited tubular reabsorption of phosphate Intravenous parathyroid extract to the intact dog was without effect upon the maximum tubular reabsorption of phosphate for 2 hours after administration Further studies will be reported on the action of parathyroid extract in the thyroparathyroidectomized dog

Pathology of an experimental flash-burn LEWIS HOGG, (by invitation), J THOMAS PAYNE (by invitation) and HERMAN E PEARSE *Univ of Rochester Atomic Energy Commission Project, Rochester, N Y* The importance of the flash burn as a clinical entity was pointed out by the Navy at Pearl Harbor, and by observers of the Hiroshima and Nagasaki casualties. An attempt was made to produce a flash burn, to study its morphology and the factors altering its healing. A series of about 75 such burns were produced on the pig, using magnesium explosions as the high intensity, short duration heat energy source. These lesions typically presented a zone of central pallor surrounded by abrupt erythema. The erythema and edema resolved over 4-7 days, leaving only a thin central crust which came free at about 10 days. Histologically, the lesions presented an abrupt, linear demarcation at their margins, as well as their depths, as manifest by hair follicle and dermal changes. Healing was by sequestration of the burned tissue, rather than by organization, and required 3-5 days. This is a unique picture and is intimately related to the transfer of heat through the cutaneous layers. The energy transfer measurements are still in progress.

Body content of radium in individuals with no known exposure J B HURSH and A A GATES (by invitation) *Dept of Radiation Biology, Univ of Rochester, Rochester, N Y* The commonly accepted maximum permissible level of radium in the body is 1×10^{-7} g. This level is about ten times higher than the lowest radium content known to have produced crippling bone lesions. It is, therefore, noteworthy that A Krebs, working in a German laboratory, measured the radium body content of eighteen individuals who died with no known radium exposure and found a range of body contents from less than 1×10^{-9} to 4×10^{-8} g radium, with an average of 1.4×10^{-8} g. If these findings have a general application, the margin between the 'safe' radium level and the level existing in 'unexposed' individuals is uncomfortably narrow. We have, therefore, repeated Krebs's measurements using crematory material available from local hospitals. Total body cremation was carried out at a temperature of 1600°F for two hours. The total ashes were weighed and ground. After mixing, an aliquot was taken for analysis. The sample was digested and put into clear solution. The radium disintegration product, radon, was allowed to accumulate for a known period of time. Radon gas was then boiled off the solution and the activity measured in an alpha counter. The results gave values from 1.3 to 3.6×10^{-10} g radium per total body with an average of 2.7×10^{-10} g. This is about two per cent of Krebs's average figure and introduces a more generous margin between the 'safe' and 'unexposed' value.

Localization of vital dyes in areas of inflammation HOWARD C HOPPS and BARBARA C REITER (by invitation) *Dept of Pathology, School of Medicine, Univ of Oklahoma, Oklahoma City, Okla* To elucidate further the mechanisms by which increased capillary permeability occurs in areas of inflammation, the manner of localization of trypan blue in dermal inflammatory lesions has been studied. In all, 58 inflammants have been investigated including such diverse agents as heat (conduction), cold, infra red and ultra violet rays, N-mustard, various cationic and anionic detergents, hyaluronidase, numerous essential oils (cantharidin, methyl salicylate, etc.), pyridine, chloroform, acetone, histamine, leukotaxine, and products of streptococcus pyogenes including intra-dermal infections as such. Quantitative data have also been secured as to the degree of localization of dye in relation to time and intensity of inflammatory reaction. These observations suggest that localization of such dyes as trypan blue differs qualitatively as well as quantitatively in response to different types of inflammatory stimuli.

Production of 'sickling' in normal red blood cells RAPHAEL ISAACS *Michael Reese Hospital, Chicago, Ill* If a drop of blood is mixed with a drop of concentrated 'fish gelatin' (e.g., Le Page's glue) the red blood cells will take on the sickle shapes at once. This phenomenon is noted in normal human blood, in the blood of animals, even those with nucleated erythrocytes, in sickle cell anemia and in spherocytosis. In an extensive list of diseases tested, the sickling response was the same. The cells are first aligned along the lines of stress in the thick jelly, but later retain the sickle form when thoroughly mixed. If the glue is allowed to dry, the sickling is preserved. In wet preparation, under a cover glass, the cells eventually become spherical, and later hemolyze. Sickling, then, is a property of all red blood cells. In sickle cell anemia and in sickle cell anemia some factor is present which makes the cells sickle under conditions which the normal cell resists.

Methionine and choline in the arrest of dietary cirrhosis of the liver in the rat ERNEST R JAFFE (by invitation), ROBERT W WISSLER (by invitation) and EARL P BENDITT *Dept of Pathology, Univ of Chicago, Chicago, Ill* An experiment with young albino rats is described in which it was possible to evaluate quantitatively the influence of methionine and choline on the progression of dietary cirrhosis. After a 70-day preparatory period on a low protein, high fat ration, the animals were offered diets containing crystalline amino acid mixtures in place of casein with various quantities of methionine, cystine, and choline for 32 days. When the rats ate 55 to 69 mg of methionine or 27 to 33 mg of choline chloride per day, cirrhosis was absent or much less marked than when they con-

sumed about 11 mg of methionine and no choline. No accentuation of hepatic fibrosis was noted that could be attributed to high levels of cystine, and the combination of cystine plus choline was not as effective in arresting the scarring as methionine and choline. The influence of methionine and choline on the cirrhosis was closely correlated with the ability of these dietary essentials to alter the large droplet fatty change present in rats after 70 days on the basal ration. These substances, perhaps through their lipotropic properties, caused a disappearance of the large globules, and this improvement in the structure of the parenchymal cells may, in part, have delayed the progression of the hepatic fibrosis.

Tocopherol requirements during the rat's menopause HANS KAUNITZ and C. A. SLANETZ (by invitation) *Depts. of Pathology and Animal Care, College of Physicians and Surgeons, Columbia Univ., New York City*. An inbred colony of albino rats was maintained for successive generations on a simplified diet supplemented by 3 mgs synthetic dl alpha tocopherol (Hoffmann-La Roche) per 100-gm diet. When the females were 3-6 months, mating resulted in 90% pregnancies, at 10-24 months, only 50% gestations (both normal or resorptions) were observed. When the tocopherol supplement was omitted, reducing the daily intake from about 300 to 30 micrograms, 50% pregnancies (nearly always resorptions) occurred when the females were 3-6 months. Those old rats on the 'complete' (3 mgs tocopherol) diets, which had become sterile, were given 30-60 mg tocopherol weekly, resulting in 16 pregnancies among 37 rats. More than half of the females on the 'complete' diet gradually developed a condition which could be termed menopause because it was associated with irregularities and finally with absence of the estrus cycle as well as with sterility. This is not necessarily a consequence of 'natural aging' because tocopherol supplements restored the estrus cycle and the fertility in a high percentage of the animals. The tocopherol requirements of the rat essential for the development of either a normal or a resorptive gestation increase steeply with age. In rats of over 1 year, they are roughly 10 times higher than at 3-6 months. This is one of the causes for the occurrence of menopause on a 'normal' diet.

Level of serum mucoprotein as indicator of disease activity in rheumatic fever V. C. KELLEY and R. A. GOOD (introduced by IRVINE MCQUARRIE) *Dept. of Pediatrics, Univ. of Minnesota, Minneapolis, Minn.* Winzler and co-workers, who determined the mucoprotein content of the serum in adult human subjects in health and in various disease states, demonstrated elevations of the levels of these proteins in malignancy, in certain acute infections, and in tuberculosis. Since they found a constant ratio to exist between total nitro-

gen, carbohydrate and tyrosine in the mucoprotein fraction, they used the relatively simple determination of mucoprotein tyrosine as an indicator of mucoprotein level. Using their methods modified to permit employment of the Evelyn photoelectric colorimeter, we determined the serum mucoprotein levels in 50 normal children and in a much larger number of children suffering from a variety of disease conditions, including rheumatic fever. Our values for normal children of different ages were in close agreement with those found in normal adults by these authors and by ourselves as well. The most notable feature of our data on sick children was the abnormally high mucoprotein levels found in a series of patients with rheumatic fever in its active phase. In comparison a similar series of rheumatic patients observed during the inactive or quiescent phase and a few patients with apparently active chorea minor showed entirely normal values. Serial determinations of the serum mucoprotein levels in a smaller group of rheumatic fever patients, followed throughout the cycle of active and inactive periods, confirmed the relationship. The degree of elevation of serum mucoprotein was found to be correlated with the state of rheumatic activity as determined by clinical manifestations and by erythrocyte sedimentation rate.

Sustained elevation of blood cholesterol and phospholipid levels in rabbits given detergents intravenously AARON KELLNER, JAMES W. CORRELL, and ANTHONY T. LADD (introduced by JOHN G. KIDD) *Dept. of Pathology, New York Hospital, Cornell Medical Center, New York City*. Sustained elevations of blood cholesterol and phospholipid were produced in rabbits maintained on a normal diet by the intravenous injection of the detergents Tween 80 and Triton A-20. A single injection of Tween 80 caused an increase in blood cholesterol and phospholipid to two to three times the baseline level, the values reaching a peak in 6 to 12 hours and returning to normal in 24 to 48 hours. Repeated injections of Tween 80 resulted in a sustained hypercholesterolemia with blood levels 5 to 15 times normal, and a parallel and somewhat greater increase in blood phospholipid levels. A single injection of Triton A-20 caused an increase in blood cholesterol and phospholipid levels to more than 5 times normal, with a peak at 2 days after injection and a return to normal after 5 to 12 days. A sustained elevation of blood cholesterol and phospholipid was maintained in 12 rabbits for 10 weeks by twice-weekly injections of Triton A-20. In most animals the blood serum became opalescent and then milky within a few hours after injection and cleared when the injections were stopped. Whether the increase in blood lipid depends on the actual presence of the detergent in the circulation, or on other factors, remains to be determined.

Fate of cancer cells implanted in susceptible and resistant hosts JOHN G KIDD and HELENE W TOOLAN (by invitation) *Dept of Pathology, The New York Hospital, Cornell Medical Center, New York City* The cells of two cancers—a mammary carcinoma and a lymphosarcoma—always grew progressively when implanted in the subcutaneous tissues of C3H mice of the sort in which they had originated, causing huge tumors that brought about death of the hosts within a few weeks after implantation. The cancer cells grew equally well for a time upon implantation in mice of the 'A' strain, but after developing into visible and palpable growths that reached 1-3 cm in diameter within 8 to 14 days, they regressed abruptly in the alien 'A' hosts, disappearing completely by the 10th to 16th days. The 'A' mice in which such tumors had regressed proved solidly 'immune' to re-implantation, no visible or palpable nodules forming after the subcutaneous implantation of large numbers of tumor cells. To learn more about the phenomena of resistance and immunity just described, a study was made of the cytological and histological changes in and around the cancer cells of regressing tumors, and those implanted in immune hosts. These findings were correlated with the viability of the cells as determined by transplantation tests. In many experiments, transplantable tumor cells were procured from regressing growths that had all but disappeared and at a time when only a few malignant cells remained, imbedded in a great mass of reactive host elements. The tumor cells likewise proved transplantable after a sojourn of 3 to 5 days or longer in the subcutaneous tissue of immune hosts.

Cardiac hypertrophy, an immediate response to Starling's Law of increased energy output of the heart CECIL A KRAKOWER and HELEN E HEINO (by invitation) *Univ of Illinois, College of Medicine, Chicago, Ill* The accepted mechanism for increasing the energy output of the heart per stroke by lengthening of the muscle fibers of the heart and that which underlies cardiac hypertrophy is the same. It has not been established experimentally, how soon cardiac hypertrophy sets in, once the energy output of the heart per stroke is increased. The speed of cardiac hypertrophy was studied in chicks standardized as to breed, age, sex, and body weight. They were fed a 6% NaCl food mixture over a period of nine hours. Food and water were then withdrawn. Observations on changes in cardiac mass were made at the end of 24 hours. It is demonstrated that in repeated trials, an increase of 7% or more in the heart weight-body weight ratio is obtained within a 24 hour period, representing an absolute increase in intracellular water, in fat-free dry substance and total nitrogen of the heart. The ratios of fat-free dry substance and nitrogen of heart to carcass were

likewise increased. It is concluded that cardiac hypertrophy is an immediate response to an increased energy output of the heart per stroke. It follows that cardiac mass in the normal individual is not stable but fluctuates with shifts in the work of the heart per beat beyond that which is customary. It will be demonstrated that a sound myocardium, responds to a given load with maximum hypertrophy within a few days, in the present experiments 20 plus % in 9 days.

Intravenous detergents in experimental atherosclerosis, with special reference to the possible role of phospholipids ANTHONY T LADD, AARON KELLNER, and JAMES W CORRELL (introduced by JOHN G KIDD) *Dept of Pathology, New York Hospital, Cornell Medical Center, New York* Rabbits were maintained on a normal diet without added cholesterol and were given twice daily intravenous injections of Tween 80 for 8 to 14 weeks. Controls were fed cholesterol but given no Tween 80. Despite the fact that the animals given detergent had considerably higher mean cholesterol levels than the controls, they had significantly less atherosclerosis. In the animals receiving detergent, the blood phospholipid levels were as high or higher than the corresponding cholesterol levels, whereas in the controls, the phospholipid levels were about half the cholesterol levels. Experimental atherosclerosis produced in rabbits by cholesterol feeding is usually accompanied by a great increase in blood cholesterol and only a slight increase in phospholipid. Other experiments in which rabbits were fed cholesterol and also given intravenous detergents indicate that despite a sustained hypercholesterolemia, the incidence and severity of atherosclerosis is decreased if the blood phospholipid is elevated concomitantly with the cholesterol. Intravenous detergents were ineffective in the resorption of atherosclerosis previously produced by cholesterol feeding. It seems probable that the cholesterol-phospholipid ratio is an important factor in experimental atherosclerosis, and that increased blood phospholipids may modify or prevent the development of atherosclerosis.

Observations on lung pathology following the inhalation of radioactive cerium HERMANN LISCO and M P FINKEL (by invitation) *Argonne National Lab, Chicago, Ill* Radioactive cerium (Ce^{144}) is one of the rare earths which is formed in the fission of uranium and of plutonium. It is a beta emitter (maximum energy 0.348 Mev) and it has a half-life of 275 days. Ce^{144} was administered to rats as an aerosol (CeO_2) in doses ranging from 3.2 to 200 μ c per animal. Although the material was deposited generally in all lobes of the lungs, its distribution was not uniform. Radioautographs showed small and large, irregularly distributed foci. A considerable portion of the inhaled cerium

remained in the lungs. However, in addition to excretion, some translocation occurred primarily to the liver, kidneys and skeleton. Histologic examinations were made of the lungs of most of the animals, especially those surviving beyond 200 days. The lesions observed will be discussed and illustrated. Particular emphasis will be placed on the occurrence of metaplastic changes in the bronchial epithelium and on malignant tumors arising therefrom.

Varying genetic resistance of rabbits to quantitative inhalation of human tubercle bacilli MAX B. LURIE, SAMUEL ABRAMSON and A. G. HEPPLESTON. *Henry Phipps Institute, Univ. of Pennsylvania, Philadelphia, Penna.* The fundamental variant tuberculosis caused by virulent bovine tubercle bacilli in highly inbred rabbits of varying genetic resistance to tuberculosis is the degree of localization of disease at the portal of entry and the chronicity of ensuing disease. Rarely, is the bovine infection completely overcome even by the most resistant family. Bovine disease in rabbits of different genetic resistance to infection differs only in degree, not in kind. It has been demonstrated that if genetically susceptible and resistant rabbits simultaneously inhale from 100 to 2000 virulent tubercle bacilli, human type, resistant rabbits overcome the infection completely so that at the end of 2 to 5 months after exposure the lungs are entirely free of any gross tuberculosis in 80% of the individuals, while in 90% of the susceptible animals there is a disease of varying extent often involving the greater part of the lung parenchyma. Thus, not only can the time necessary for determining resistance be greatly shortened, but the distinction between genetically resistant and susceptible rabbits becomes an all or none difference in the great majority of individuals. There is evidence that genetically resistant animals have an innate capacity to destroy or inhibit growth of inhaled human type tubercle bacilli more effectively than susceptible rabbits. Furthermore, and perhaps as a consequence of this differing capacity, genetically resistant rabbits tend to develop allergic sensitivity to tuberculin more rapidly than susceptible rabbits under these conditions.

Studies on the pathogenesis of experimental necrotizing arteritis J. H. McCORMICK, JR. (by invitation) and RUSSELL L. HOLMAN. *Dept. of Pathology, Louisiana State Univ. School of Medicine, New Orleans, La.* Previous studies from this laboratory have shown that acute necrotizing arteritis can be produced with regularity in dogs by feeding them a specified high fat diet for a period of 8 weeks or longer then sacrificing them through renal damage. To determine whether damage to tissues and organs other than the kidney would precipitate the lesions in properly fed dogs, 4 such animals were subjected to light chloroform

anesthesia for periods totalling 9 to 28 hours in 6 to 20 days. None of these 4 dogs showed either gross or microscopic lesions in the arterial system. Another group of 3 properly fed dogs were subjected to severe inflammatory reactions, one by means of sterile abscesses induced with turpentine and 2 by bacterial infections. None of these dogs showed arterial lesions. These experiments tend to emphasize the importance of the kidney in the pathogenesis of necrotizing arteritis, and suggest the possibility that the proximal convoluted tubules elaborate a substance that is necessary for the proper utilization of certain lipid substances.

Influence of alloxan diabetes of cholesterol atherosclerosis in the rabbit HENRY C. MCGILL (by invitation), LOUIS E. PARRISH (by invitation) and RUSSELL L. HOLMAN. *Dept. of Pathology, Louisiana State Univ. School of Medicine, New Orleans, La.* Nine control rabbits fed Rockland rabbit diet with 0.3–5 gm. of cholesterol in olive oil per day were sacrificed after intervals of 38 to 72 days on this diet. There was an average gain in body weight of 38% and an approximate seven-fold increase in total blood cholesterol. All 6 of these animals sacrificed beyond the 48th day showed gross or microscopic atheroma in the aorta and elsewhere, and the degree of these lesions increased with time. Eight rabbits of similar age and original body weight were injected two or more times with alloxan (180 to 385 mg/kg. total) and after a satisfactory diabetic state was established they were fed the same diet and cholesterol in oil as the control animals. These diabetic rabbits were sacrificed after intervals of 18 to 98 days. Six of the 8 rabbits lost weight but 2 of them showed weight gains comparable to the control rabbits. Despite a ten-fold increase in the blood cholesterol level in this group only the rabbit fed for 98 days (which lost 10% in body weight) showed microscopic arterial lesions. Three rabbits injected with alloxan failed to develop sustained diabetes and had lesions comparable to the controls when sacrificed at 40, 52, and 69 days respectively. Contrary to anticipation these results indicated that the diabetic state induced by alloxan retards in both time and degree the development of cholesterol atherosclerosis in the rabbit. These experiments confirm the results of Duff and his co-workers.

Experimental papillary necrosis of the kidney EMANUEL E. MANDEL (by invitation) and HANS POPPER. *Dept. of Pathology, Northwestern Univ. Medical School, the Hektoen Institute for Medical Research of the Cook County Hospital and the U. S. Public Health Service, Chicago, Ill.* Necrosis of the renal medulla has been reported in old European papers to be produced in experimental animals by the administration of vinylamine. In order to study pathogenesis and functional changes incident to such a lesion, vinylamine (ethyleneimine) was

given to 20 rabbits in single or divided doses of 0.005 to 0.03 gm/kg body weight. On the first day following injection of a lethal dose, excessive hyperemia of all medullary vessels occurred, associated with edema and hemorrhage particularly around the bundles of vasa recta at the cortico-medullary junction. The cortex showed striking ischemia except for distended veins. Necrosis of epithelium of the proximal convoluted tubules was often present. In later stages (3-14 days after intoxication), when the cortical epithelium appeared either almost or completely normal or showed evidence of regeneration, conglutination thrombi of erythrocytes were seen in engorged medullary vessels. There were well circumscribed foci of ischemic necrosis of varying size in the papillae. These animals did not develop anuria but showed albuminuria, hematuria and progressive azotemia with almost complete abolishment of renal concentration power as indicated by a urine/plasma quotient of close to unity. In animals surviving the intoxication more than 2 weeks, fibrous scars were found in the papillae and also replacing the vasa recta bundles. These findings appear to throw light both upon a vascular pathogenesis of human papillary necrosis and upon the renal functional impairment occurring in predominantly medullary injury. They, furthermore, illustrate the duality of renal circulation (Trueta).

Hypoprothrombinemia due to loss of intestinal lymph J. D. MANN (by invitation), F. D. MANN (by invitation) and J. L. BOLLMAN *Mayo Foundation, Rochester, Minn.* When all of the intestinal lymph of the rat was drained externally, marked hypoprothrombinemia, as determined by the two-stage method, developed rapidly, usually within 24 hours. If adequate amounts of vitamin K were administered parenterally a normal level of prothrombin was maintained, despite loss of lymph and even of considerable amounts of blood as well. Transfusion of twice the animal's normal plasma volume did not maintain normal prothrombin while lymph was lost. Under the conditions of these experiments it appeared that vitamin K was absorbed practically exclusively through the lymph and very little of it was stored, while the turnover of prothrombin was extremely rapid.

An additional thermostable component in the mechanism of leukocytosis with inflammation VALY MENKIN *Agnes Barr Chase Foundation for Cancer Research, Temple Univ. School of Medicine, Philadelphia, Penna.* The leukocytosis-promoting factor (LPF), described previously, offers in part a reasonable explanation for the mechanism of leukocytosis with inflammation. Nevertheless, an acute experimental inflammation is frequently associated with a leukocytosis of such a high level that it cannot always be explained by liberation of LPF. This is especially seen in the later stages of

an inflammatory state when the exudate tends to be at an acid pH, and from which the LPF is not always readily recovered. It has been observed that the non-injurious pyrogenic factor, pyrexin, frequently recovered from acid exudates, induces not only an elevation in temperature, but also an initial leukopenia due to the presence of the leukopenic factor, described previously. The initial leukopenia is subsequently followed by a marked leukocytosis. Boiling pyrexin fails to inactivate this leukocytosis-promoting component. This latter is evidently thermostable. Its effect is very rapid. Even one hour following administration of boiled pyrexin, the effect of the thermostable component of the leukocytosis-promoting factor is manifested by the discharge of immature polymorphonuclear leukocytes. This thermostable component is found in boiled whole acid exudate. In alkaline exudates it is less pronounced, and in such boiled exudates only the discharge of immature leukocytes may be encountered. This thermostable component has been observed in the inflamed pleural cavity of dogs, inflammation being induced with either turpentine or croton oil in olive oil and in the inflamed pleura of guinea pigs with the reaction caused with croton oil in olive oil. The mechanism of leukocytosis with inflammation seems referable to two components: a thermolabile component distributed between the α 1 and α 2 globulins of exudate and a thermostable component associated with pyrexin in the euglobulin fraction found particularly in acid exudates.

Effects of thyroid feeding on histologically normal islets of rats receiving small doses of alloxan DAVID W. MOLANDER (by invitation) and ARTHUR KIRSCHBAUM *Dept. of Anatomy, Univ. of Minnesota Medical School, Minneapolis, Minn.* Impairment in glucose tolerance appeared in rats receiving 4 intravenous injections of 20 mg/kg of alloxan on alternate days. Fasting blood sugar levels were not elevated. Microscopically the pancreatic islets were normal. Rats receiving 10 injections of the same dose of alloxan showed glucose tolerances similar to those found in animals receiving four doses. Beta cell degeneration was present, however, in the islets. Neither glucosuria, polyuria, nor polydipsia occurred in either the 4 or 10 dose animals. Extensive beta cell degeneration was observed in rats receiving one dose of 30 mg/kg. These rats exhibited persistent hyperglycemia and glucosuria, and decidedly altered glucose tolerance. Growth was stunted, whereas it was normal in animals receiving the 4 or 10 injections. If thyroid (0.1 gm/kg daily by stomach tube for one month) was fed to rats following the 4 doses of alloxan, glucosuria and fasting hyperglycemia occurred. This condition persisted until the rats were autopsied one month after the last feeding. If rats were adrenalectomized preceding the administra-

tion of thyroid, clinical diabetes did not appear. The islets of thyroid-fed alloxanized rats revealed a reduction in the number of beta cells. In the rats that were adrenalectomized preceding thyroid treatment, and in which clinical diabetes did not appear, no changes in the islets were observed. Thus, by functionally altering the beta cells with small repeated doses of alloxan, the added metabolic strain imposed on islet tissue by thyroid feeding was detectable. Lower blood sugar (reduced gluconeogenesis) following adrenalectomy was probably important in preventing beta cell damage.

Induction of hepatic carcinoma in rats by 4-dimethylaminobenzene-1-azo-1-naphthalene. A S MURRAY and H I FIRMINGER (introduced by HAROLD L STEWART) *National Cancer Institute, Bethesda, Md.* Azonaphthalene (4-dimethylaminobenzene-1-azo-1-naphthalene) was fed to 80 Osborn-Mendel rats, in the dose of 0.075 gm/100 gm of diet for 8 months. The dye was suspended in corn oil, and this in turn was incorporated in a basic diet consisting of casein, sugar, vitamin mix, and salt mix. Following the azonaphthalene diet period, the animals were returned to their normal laboratory diet of Purina Chow pellets. They were examined at regular intervals, and the date of the first palpable tumor was noted. The clinical diagnosis of the tumor was confirmed at autopsy by microscopic examination in all cases. Fifty-six animals have been autopsied to date and 11 tumors have been found, an incidence of 19.5%. In this series, the first tumor appeared 8 months after the start of the experiment. If this interval is taken as the latent period for tumor induction by this compound, and the percentage of tumor incidence is then recalculated on the basis of those animals surviving the incubation period, the incidence of the tumor increases to 31%. The changes in the liver were similar to those induced by paradi-methylaminoazobenzene. Microscopic examination showed fatty change, fibrosis, bile duct proliferation, cirrhosis, cyst formation, and carcinoma. Most of the tumors were hepatic cell carcinomas. They infiltrated the adjacent tissues, and metastasized to the peritoneum, mesentery, and the lungs.

Renal cytoplasmic inclusions following the administration of large doses of streptomycin. CHARLES W MUSHETT and ROBERT B STEBBINS (by invitation) *Merck Institute for Therapeutic Research, Rahway, N. J.* Repeated subcutaneous injection of streptomycin either as the sulfate or the calcium chloride complex has resulted in the appearance of acidophilic 'colloid-like' droplets in the cytoplasm of the renal tubular epithelium of rats and dogs. The droplets, varying in size from small granules to relatively large globular bodies, have been seen within one week when daily injections

of drug (400 mg base/kg body weight) were given. After discontinuance of treatment in rats dosed daily for 21 days, it was observed that the droplets became smaller in size and had disappeared within 4 weeks. With hematoxylin-eosin stain the inclusions have a deep pink color, some give a positive reaction for hemoglobin by the Dunn-Thompson technique, they are not visualized by the usual fat staining methods. Salts of dihydrostreptomycin, the reduced form of streptomycin, also produced these inclusions. The feeding of natural stock diets, highly purified diets or diets containing 5% liver powder had no influence on the appearance of the inclusions. No abnormalities in renal function were observed in dogs whose kidneys were found to contain the 'colloid-like' cytoplasmic inclusions. The nature of the renal inclusions observed after treatment with streptomycin or dihydrostreptomycin is as yet undetermined.

Comparison of different lots of bacitracin for nephrotoxicity to rats and mice. A A NELSON and E C HAGAN (by invitation) *Division of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D. C.* Five commercial lots of bacitracin, suspected of varying in their degree of nephrotoxicity when given parenterally in man, were studied. Microscopic sections were made from 140 animals. All 5 lots caused severe kidney damage when 5000 U/kg in 2% solution were injected intraperitoneally twice a day in mice for 3 days. Variation in kidney damage between lots was no greater than that between different batches of mice when the same lot was used. The basic lesion was necrosis and sloughing of the convoluted tubular epithelium, evident as early as 1 hour after a single injection. Morphological effect paralleled dosage, and our impression was that when a certain concentration of bacitracin occurred in the tubule there was a direct toxic effect on the epithelium. Saline solutions were slightly less toxic than water solutions. In a general way the histological appearance was similar to that described by Scudt et al (*Proc Soc Exper Biol & Med* 64: 503 and 66: 558, 1947). In our rats, however, lesions were not 'insignificant', with equal dosage, rats showed even greater kidney lesions than did mice. Nephrotoxicity in rats from intramuscular administration was as great as from intraperitoneal, in mice it was much less. Intramuscularly, local inflammatory reaction was severe in rats and less so in mice, intraperitoneally, local reaction was slight. Organs other than kidney showed infrequent or little effect. Limited study of repair showed that in mouse kidneys the bacitracin picture persisted for about 15 days, changing after 30 days into one of a nonspecific nephritis.

Bone deposition of uranium. W F NEUMAN, M W NEUMAN, E R MAIN and B J MULRYAN

(introduced by F S ROBSCHT-ROBBINS) *Dept of Radiation Biology, School of Medicine & Dentistry, Univ of Rochester, Rochester, N Y* Previous studies have indicated that the major site of long-term storage of uranium injected into animals was the skeleton. Once deposited, the uranium was mobilized very slowly and underwent very little redistribution within the skeleton itself. A series of studies *in vitro* was conducted on the mechanism of this skeletal deposition. The results of these experiments indicate that uranyl ions undergo exchange with calcium ions in the surfaces of the bone, mineral crystals. In this exchange, uranium apparently combines with two adjacent phosphate groups in the mineral surface to form a but slightly dissociated complex.

Reticulocyte ripening and nutrition in anemic dogs A NIZET (introduced by F S ROBSCHT-ROBBINS) *Univ of Rochester School of Medicine and Dentistry, Dept of Pathology, Rochester, N Y* The ripening time of the reticulocytes has been measured by a technique previously described in anemic dogs and doubly depleted dogs (anemia and hypoproteinemia). Anemia is produced by blood withdrawal, double depletion by blood withdrawal plus a non-protein containing diet. The progressive disappearance of the various reticulocyte groups is studied in heparinized blood samples at body temperature. In the anemic dogs receiving a basal diet containing proteins the ripening time is the same as in non-anemic dogs, regardless of the supplementary diet factors. In the anemic hypoproteinemic dogs (double depletion) in contrast receiving a non-protein basal diet the ripening time depends upon the supplementary diet factors. With the non-protein diet alone in these doubly depleted animals the ripening is almost completely blocked. Following administration of poor supplementary diet factors (low hemoglobin regeneration) the ripening time is greatly prolonged. With an optimum supplementary diet (maximum hemoglobin regeneration) the ripening time is normal. The rate of hemoglobin regeneration *in vivo* and the ripening time of the young erythrocytes *in vitro* coincide very well.

Histopathology of the liver following histamine infusion W G NOTHACKER and RALPH W BRAUER (introduced by RUSSELL L HOLMAN) *Depts of Pathology and Pharmacology, Louisiana State Univ School of Medicine, New Orleans, La* When histamine diphosphate was infused continuously into the portal vein of a dog under sodium pentobarbital anesthesia, at such a rate as to depress the mean arterial blood pressure to approximately 50% of the initial level, there was a fall in the portal venous pressure, an increase in lymph flow from the liver, and a reduction of the rate of bromsulphthalein removal from the blood plasma. In animals sacrificed after 4 hours or more of such

infusion, the liver was enlarged, and mottled red and red brown with prominent portal areas. Upon histological examination these livers showed neutrophils and lymphocytes about the portal veins, dilatation of portal lymphatics, leukostasis of neutrophils in the sinusoids, constriction of central veins and occasional hemorrhages into the portal areas. When histamine infusion was stopped, at any time during the experiments, the mean arterial blood pressure regularly rose to the initial level within ten minutes or less and the animal survived. Control animals subjected to the same experimental procedures but infused with normal saline showed none of the above physiological and anatomical changes. These studies indicate that histamine in sublethal doses is capable of producing definite liver injury.

Replacement of a portion of common bile duct by a segment of uterine horn CHARLES M O'LEARY (by invitation), WILLIAM T SNODDY (by invitation), and BÉLA HALPERT *Depts of Surgery and Pathology, Univ of Oklahoma School of Medicine, Oklahoma City* The right uterine horn of the dog was resected with its blood supply from the ovarian artery left intact. The common bile duct was severed near its junction with the duodenum and the duodenal end ligated. The proximal end of the common bile duct was then telescoped into the proximal end of the uterine horn while the distal end of the horn was pulled through a longitudinal slit made in the duodenal wall about 2 cm anterior and medial to the choledochoduodenal junction. Both ends of the uterine horn were secured in place by cotton sutures. Of 20 dogs surviving the operation 12 lived for 3 to 21 days, the rest were sacrificed between 4 and 27 weeks following the operation. Detailed morphologic studies are in progress to determine the mechanism by which the continuity of the flow of bile into the duodenum was maintained and the effects of the replacement of the terminal segment of the common bile duct on the biliary system.

Restoration of estrous cycle by alpha tocopherol in old rats S Y P'AN, HANS KAUNITZ, and C A SLANETZ (by invitation) *Depts of Pharmacology, Pathology, and Animal Care, College of Physicians and Surgeons, Columbia Univ, New York City* An inbred colony of albino rats was maintained for successive generations on a simplified diet containing 3 mg (synthetic alpha tocopherol (Hoffmann-La Roche) per 100 gm, this permitted a daily intake of approximately 300 micrograms of tocopherol as usually provided for laboratory rats. Daily vaginal smears were made on 64 females of 10-20 months for 4 weeks or more. In 16, the estrous cycle was of 4-5 days duration, in 34, it lasted more than 8 days, and in 15 of this latter group, it lasted longer than 17 days in 80% and more than 12 days in 20%. The latter 15 females received 30-

60 mgs alpha tocopherol weekly by mouth. In 3 rats, cycles of 4-5 days and in 5, cycles of 6-8 days were observed within 2 weeks after treatment was begun. There was no change in the remaining 7 animals. It is improbable that the shortening of the cycle was due to spontaneous changes because 4 untreated controls with cycles of 9-12.5 days were smeared during the period of observation with lengthening of the cycles. It seems evident that, in a high percentage of old rats maintained on a diet with 'normal' tocopherol supplement, lengthened estrous cycles may occur which can frequently be shortened by additional alpha tocopherol.

Blood cholesterol value of normal men in relation to their basal metabolic rate. ANNIE LAURIE PEELER (by invitation), OPAL E HEPLER, VELMA MILLER KINNEY (by invitation), LILLIAN E CISLER (by invitation), and FREDERIC T JUNG (by invitation) *Depts of Pathology and Physiology, Northwestern Univ Medical School and Passavant Memorial Hospital, Chicago, Ill.* Because of the large range of normal cholesterol values the correlation was determined between the blood cholesterol of normal men and their basal metabolic rates. Bloor's method adapted to the Evelyn photoelectric colorimeter was used to determine cholesterol in serum. Values for 73 male medical students ranged from 131-303 mg/100 ml of serum with a mean of 189 mg and a standard deviation of ± 33 . Four fell below 150 and 6 above 250, leaving 86% with a range from 150 to 250 mg. The metabolism tests were performed under basal conditions using a Benedict-Roth machine. The results presented are the percentages above and below normal using the Boothby and Sandiford modification of Dubois standards. Values for 73 men ranged from -24.9 to +10% with a mean of -9.5% and a standard deviation of ± 7.2 . No correlation was found between these basal metabolic rates and cholesterol values as shown by the correlation coefficient of -0.10. Both cholesterol and basal metabolic rates were repeated on 40 of the men after a 38-day period which included 2 weeks of vacation. The coefficient of correlation between the first and second cholesterol values was +0.73 which indicates that the blood cholesterol is maintained at a fairly stable level. This was also true, to a lesser extent, of the basal metabolic rates which gave a correlation coefficient of +0.65 between the first and second periods.

Quantitative correlation between results of hepatic tests and morphologic liver cell damage. HANS POPPER, FREDERICK STEIGMANN and PAUL B SZANTO (by invitation) *Hektoen Inst for Medical Research of the Cook County Hospital, the Dept of Pathology of Northwestern Univ Medical School and the Dept of Internal Medicine of Univ of Illinois College of Medicine, Chicago, Ill.* The degree of liver cell damage was graded 0 to 3 plus

in 257 liver biopsy specimens obtained from patients with various diseases, mostly hepatobiliary in nature. The results were compared with those of a series of hepatic tests performed simultaneously with the biopsy. In confirmation of previous studies concerning correlation of presence or absence of pathologic findings with results of hepatic tests, it was noted that the higher the grade of liver cell damage in a group, the higher the average of the cephalin flocculation, thymol turbidity, serum globulin, urinary urobilinogen, alkaline phosphatase, prompt reacting and total bilirubin, and the lower the albumin, albumin/globulin ratio and prothrombin time. No parallelism was found with total serum protein, total cholesterol, non-protein nitrogen, sedimentation rate and fecal urobilinogen. The described parallelism was not necessarily present in individual cases. Moreover, in extrahepatic biliary obstruction without secondary infection, cephalin flocculation and thymol turbidity did not parallel the degree of liver cell damage, the cephalin flocculation being negative and the thymol turbidity only slightly elevated even with severe damage. Contrarily, the results of these two tests paralleled the degree of liver cell damage if bacterial infection complicated extrahepatic obstruction. To exclude liver cell damage, cephalin flocculation and urinary urobilinogen appeared the most valuable tests. The number of tests with abnormal results paralleled the degree of liver cell damage in the different groups. In general, the frequent exception in individual cases do not contradict a general tendency to a quantitative relation between functional and structural hepatic alterations.

Electron microscopy of clinical marrow aspirates. J W REBUCK and H L WOODS (introduced by F W HARTMAN) *Dept of Labys, Henry Ford Hospital, Detroit, Mich.* Direct electron microscopy of sternal aspirates was accomplished as follows. After aspiration of the specimen the customary air-dried smears were prepared from a portion for light microscope studies. The remaining material was utilized, with a modification of Schleicher's technic, for electron microscope studies. One or more gross marrow units were selected and affixed to the blunt end of a wooden applicator. Imprints were then made by touching the marrow unit lightly against formvar-covered glass slides. The marrow cells adherent to the surface of the formvar were fixed over osmic acid vapor and washed in distilled water. The specimens were mounted directly by the modified stripping technic which we have previously reported. Electron micrographs of hematocytologic features were thus obtained. Developing neutrophil granules were observed to be more vacuolar than granular in structure. The bizarre nuclear structure of leukemic reticulum cells from a case of reticular myelosis was depicted.

Superimposition of small osmophilic spherules was noted. Myeloma cells from a case of multiple myeloma were micrographed. A small, extremely dense particulate substance presented in the cytoplasm of such a cell. In one such case complicated by an acquired hemolytic anemia, interesting structural changes were present in erythrocytes individually and in their agglutinated relationships. Upon erythrocytic desiccation in rouleaux-like aggregates, hemoglobin shrinkage resulted in delineation of the isolated corpuscular 'membrane'. The thickness of this human surface ultrastructure was measured as being between 330 and 1000 Å with a mean of about 550 Å.

Effect of antihistamine on the localization of trypan blue in xylene treated areas of skin. R. H. RIGDON *Laby of Exptl Pathology, Medical Branch, Univ of Texas, Galveston, Texas*. Localization of dye in areas of skin injected with histamine (*J Lab and Clin Med* 27: 1554, 1942) and in areas of inflammation produced by xylene (*Arch Surg* 41: 101, 1940) has been studied. In the latter it was shown that localization and concentration of this dye was determined by the interval between the application of xylene and the injection of the dye. Furthermore, the localization of the dye was not related to the presence of hyperemia. The influence of antihistamine on the hyperemia produced by xylene and the localization and concentration of dye in these areas were studied in the rabbit. Pyrrolidineethylphenothiazine hydrochloride (Pyrrolazate) and N,N-Dimethyl-N' (alpha-pyridyl)-N'-(alpha-thenyl)-ethylenediamine hydrochloride (Thenylene) were dissolved in saline (10 mg/ml). The former was given intravenously and the latter intravenously and intraperitoneally in large amounts. The antihistamine was given frequently before the intravenous injection of trypan blue (10 ml of a 0.5% solution). Xylene was applied to the skin with a cotton applicator at intervals preceding the injection of the dye. Reaction to the xylene was the same in antihistamine treated animals as in the controls. Furthermore, the localization and concentration of trypan blue was the same as in the controls. Trypan blue localized and concentrated at the site of intradermal injection (0.2 ml) of antihistamine. It is suggested that histamine is not the primary factor responsible for the localization and concentration of trypan blue in areas of inflammation produced by xylene and, furthermore, antihistamine, when injected intradermally in the rabbit, causes a localization and concentration of dye in a manner similar to the intradermal injection of histamine.

Multiple injections of potassium as a test for adrenocortical function, with modifications induced by desoxycorticosterone. THEODORE ROBERTSON (introduced by JOHN G. KIDD) *Dept of*

Pathology, New York Hospital—Cornell Medical Center, New York City. As a means of studying the function of the adrenal cortex a modification has been made of the potassium toxicity test previously employed by others. Four intraperitoneal injections of potassium chloride solution were given at 2-hour intervals to mature rats and mice. Dosage was calculated in milligrams of KCl/10 gm of body weight. Significant differences were found when the test was applied to normal and adrenalectomized animals. For the L D 50 in normal rats was about 4.5 mg/10 gm, and in normal mice was slightly less than 5 mg/10 gm, whereas in adrenalectomized animals given salt and tested on the sixth postoperative day, the L D 50 values were approximately 2.0 and 2.6 respectively in the two species. A consistently increased resistance to potassium was obtained by the administration of small amounts of desoxycorticosterone acetate in various ways to normal and adrenalectomized animals. The only variation attributable to sex was found in adrenalectomized rats about 11 weeks old. When tested with 2 mg KCl/10 gm there was a 90% mortality in males (18 of 20) and a 15% mortality in females (2 of 13). The results obtained with the potassium toxicity test suggest an ovarian influence on potassium metabolism as an addition to those influences previously recognized. The test has also been applied with interesting results to animals in which a depletion of the zona glomerulosa of the adrenal cortex had been effected by means of pellets containing desoxycorticosterone.

Intradermal reaction to streptococcal thermal antibody and antigen in persons having epidemic respiratory infections. EDWARD C. ROSENOW *Bacteriological Research, Longview Hospital, Cincinnati, Ohio*. The solutions of thermal antibody and of antigen injected intradermally consisted of the bacteria-free supernatants of saline suspensions of streptococci isolated in studies of respiratory infections. The former after autoclaving suspensions containing twenty billion streptococci/ml for 96 hours and adding an equal volume of saline containing 0.4% phenol, the latter after heating suspensions containing ten billion streptococci/ml at 70°C for one hour and adding 0.2% phenol. Three hundredths ml of each and of control solutions were injected into the skin of the anterior aspect of the forearm of 272 persons having respiratory infection and of 483 well persons. Reactions to the 'respiratory' thermal antibody indicating specific antigen in skin or blood and of a streptococcal infection occurred in nearly all persons having respiratory infection. The reactions were largest during the acute stage of the disease and gradually diminished as recovery ensued. In sharp contrast reactions to 'respiratory' antigen indicating antibody were minimal at the onset, in-

creased as recovery occurred and then diminished as antigen disappeared. The incidence of significant reactions to the 'respiratory' antibody indicating antigen in well persons during summer was minimal. It increased in autumn and remained relatively high during winter and spring but was uniformly less in persons having symptoms of respiratory infection. Reaction to the 'respiratory' antigen was absent or least pronounced in well persons remote from respiratory infections and increased with the seasonal incidence. Reactions in well persons to 'poliomyelitic' streptococcal antibody and antigen were in reverse of those to 'respiratory' antibody and antigen.

Contagiousness of coccidioidomycosis. SOL ROY ROSENTHAL *Univ of Illinois, College of Medicine, Chicago, Ill.* Experiments conducted in 3 phases show that coccidioidomycosis is a contagious disease. 1) Spherule containing exudates from humans or guinea pigs when instilled into the trachea of guinea pigs produced a primary form of the disease very similar to that found in humans. 2) Spherule containing exudates of humans kept in the refrigerator for periods up to 110 days failed to produce mycelial threads and chlamydozoospores but retained their spherule forms that were infective to guinea pigs. Spherule containing sputum exposed out of doors to the shade or the sun with or without earth for periods up to 230 days retained their spherule forms, albeit in a certain percentage of cases mycelial forms were found. 3) In a limited number of cases placing normal guinea pigs in the same cages with animals infected intratracheally with the spherules of *coccidioides immitis* resulted in infection of the control animals.

Electrocardiograms of normal and malarial infected monkeys. ARTHUR RUSKIN (by invitation) and R. H. RIGDON *Heart Station and Lab of Exptl Pathology, Univ of Texas, Medical Branch, Galveston, Texas.* Electrocardiograms in 14 normal *M. rhesus* monkeys weighing from 2 to 6 kg simulated those of normal humans with the following differences. The QRS wave was usually of very low voltage in Lead I. The T wave in Lead I was likewise usually very low. It was flat in 7 monkeys. However, in 1 it was slightly negative on another occasion. The T wave in Lead II was flat in 2 cases, in both slightly negative on other occasions. T4 was flat in 2 animals and slightly negative in one. These findings controvert those of deWart and Storm. Heart rate varied from 190 to 280, P-R interval from 0.06 to 0.10 sec, QRS from 0.02 to 0.04 sec, Q-T from 0.14 to 0.18 sec, the axis from 50° to 115° . Marked S-T segment depression occurred particularly in Lead II and III in 6 cases. An auricular ectopic beat was the only arrhythmia noted. Electrocardiograms in 12 monkeys infected with *P. knowlesi* did not vary significantly from normal. This is consistent with

the absence of specific pathologic lesions in the heart of malarial infected monkeys. T waves in Lead I were flat in 6 of 12 infected monkeys. In 2 of the same group on different days T waves in Lead I were negative, however, both monkeys showed similar findings before infection. In 2 monkeys with severe parasitemia, the Q-T intervals were 0.20 at a ventricular rate of 188, and 0.23 at a rate of 159. One also showed left axis deviation of -48° , another very ill animal had an axis deviation of -40° . With these three exceptions, electrocardiograms in malarial infected monkeys were similar to normals.

X-ray induced developmental abnormalities in the mouse. LIANE BRAUCH RUSSELL (introduced by F. S. ROBSCHT-ROBBINS) *Biology Division, Oak Ridge National Laboratory, Oak Ridge, Tenn.* In an attempt to determine the effect of penetrating radiation on developing mouse embryos, pregnant females were irradiated at various stages of gestation. Each female was given a single exposure to 250 krp x-ray total body irradiation, doses ranging from 200-500 r at an intensity level of around 80 r/min. Gestation was timed from the observation of a vaginal plug and the stages examined cover almost the entire range of embryonic life. Highly inbred C57 Black strain females, made pregnant by NB strain males, yielded the genetically uniform F₁ fetal population. Except for a few cases in which the litters were raised, the irradiated fetuses were allowed to develop only to birth (or the expected date of birth), at which time they were carefully examined externally and then processed to give cleared and stained skeletal preparations. Our results indicate that certain structures are sensitive to x-ray effect only during definite periods in development. Dosage-effect relations at particular stages have proved to be interesting. It is hoped that the determination of sensitive stages for each structure, the entire syndrome produced at a particular stage and the order in which certain changes are produced—all considered in conjunction with the known facts of normal development and of hereditary abnormalities—may shed some light both on the nature of the radiation effect and the nature of development.

Prompt and indirect reacting serum bilirubin in jaundice. FENTON SCHAFFNER (by invitation), HANS POPPER and FREDERICK STEIGMANN *From the Hektoen Inst for Medical Research of the Cook County Hospital, the Dept of Pathology of Northwestern Univ Medical School, and the Dept of Internal Medicine of Univ of Illinois College of Medicine, Chicago, Ill.* Serum bilirubin determinations (1 minute and total) were obtained on 195 jaundiced patients with cirrhosis (152), acute hepatitis (171) and extrahepatic biliary obstruction (99). Results were correlated in 132 instances with liver biopsies. The ratio of prompt reacting to total bili-

rubin followed similar distribution curves with almost half the values lying between 40 and 50%. Too few cases of hemolysis were observed to evaluate statistically but in each instance the ratio of prompt to total bilirubin was below 15%. When the ratio was plotted against total bilirubin, ratios ranged in random fashion between 12 and 73% when the total was below 10 mg/100 cc. When above this, 82.5% of the ratios were between 30 and 50%. As the level rose, the ratio fell. It was below 40% in 65% of the determinations when the total was above 40 mg/100 cc. No relation between ratio and degree of liver damage was noted. The only significance of an elevated prompt bilirubin in the presence of jaundice is its exclusion of hemolysis. This does not support the view that bilirubinemia arises in a different manner in parenchymal and obstructive jaundice. The evidence suggests that indirect bilirubin is changed to prompt reacting in the Kupffer cells from where it is transmitted to the liver cells. Inability of Kupffer cells to accept indirect bilirubin explains the elevated indirect level in non-hemolytic jaundice, while leakage from the Kupffer cells or regurgitation explains the elevated prompt levels.

Preparation and properties of mammalian striated myofibrils ARMIN F. SCHICK, (by invitation) and GEORGE M. HASS, *Rush Dept. of Pathology, Presbyterian Hospital, and the Dept. of Pathology, Univ. of Illinois College of Medicine, Chicago, Ill.* A physico-chemical method for isolation and purification of myofibrils from mammalian skeletal and cardiac muscle has been devised. Blocks of living muscle were frozen and cut into sections with a microtome. Sections were transferred to a proteolytic enzyme buffer solution (0°C, pH, 7, ionic strength, 0.25). After 30 to 45 minutes, the myofibrils were separated by mechanical agitation. Then, the segregated myofibrils were separated from other components of muscle by centrifugation. The isolated myofibrils obtained in large quantities had characteristic properties. They varied in length and breadth but retained microscopic structural detail, plasticity and birefringence, characteristic of myofibrils in their intracellular location. They were soluble in a slightly alkaline reagent (0.5 N KCl - 0.03 N sodium bicarbonate) giving viscous solutions which displayed birefringence of flow. In buffer solutions with an ionic strength of 0.15, myofibrils dissolved acid to pH 4.0 and alkaline to pH 10.0. In phosphate buffer solutions with an ionic strength of 0.5, myofibrils dissolved when solutions were alkaline to pH 6.3. In phosphate buffer solutions with ionic strength increased from 0.15 to 0.5 by addition of potassium chloride, myofibrils were soluble when solutions were alkaline to pH 6.0. Isolated myofibrils, although probably modified by tryptic action and mechanical agitation during isolation at 0°C, ex-

hibited property of contractility when placed in solutions of adenosine triphosphate. Under these conditions, myofibrils isolated from skeletal muscle contracted rapidly so that long fibrillar structures were converted irreversibly into spherical masses.

Electrophoretic findings in normal and abnormal pregnancy NEVIN S. SCRIMSHAW (by invitation) and ERIC L. ALLING, *School of Medicine and Dentistry, Univ. of Rochester, Rochester, N. Y.* Electrophoretic patterns of nearly 200 normal and abnormal pregnant women reveal a tendency for albumin values to be lowered in preeclampsia. In 46 of 52 mild and severe pre-eclamptics, the albumin value was below 2.80. It was below this figure in only 10 of 77 apparently normal pregnancies. The pattern in pregnancy with essential hypertension does not differ from that of normal pregnancy. However, when pre-eclampsia is superimposed on previously existing hypertension, the pattern is that of pre-eclampsia. This is strong evidence that pre-eclampsia and essential hypertension are separate conditions which frequently co-exist during pregnancy. It is usually possible to determine by means of the electrophoretic pattern whether a blood pressure elevation late in pregnancy actually represents pre-eclampsia. In occasional cases, the lowering of albumin has been noted to precede the appearance of clinical signs and symptoms of preeclampsia. The changes in the globulin fractions are less consistent, but the shapes of the peaks as well as the absolute values may be of significance. If a small amount of normal hemoglobin is added to normal plasma before electrophoresis, it migrates with, or just behind, α_2 globulin. In most cases of severe pre-eclampsia, normal hemoglobin so added, migrates more slowly, with β globulin. After delivery the migration soon becomes normal. This phenomena has also been observed in all cord blood examined. It has never been observed in plasma from pregnant women without pre-eclampsia.

Chorionic gonadotrophin as luteotrophin in women ALBERT SEGALOFF, CORNELIA J. GASKILL (by invitation), WILLIAM STERNBERG (by invitation), and RICHARD L. COPPEDGE (by invitation), *Depts. of Medicine, Physiology and Pathology of Tulane Univ., the Alton Ochsner Medical Foundation, and the Charity Hospital of Louisiana, New Orleans, La.* Five patients were given chorionic gonadotrophin (A.P.L.—Ayerst, McKenna and Harrison) in a dosage of 10,000 i.u./day starting after the ovulatory rise in the cycle. Preliminary studies and studies during treatment were made on the urinary excretion of gonadotrophic hormones, 17-ketosteroids, glycogen depositing steroids (cortin) and prolactin. Endometrial biopsies were obtained in the previous cycle and during therapy. Three of the patients required gynecologic surgery and were given the chorionic gona-

drotrophin up to the day of surgery, and the surgical specimen studied. There were no significant changes in the urinary excretion of 17-ketosteroids or cortin. There was a small but consistent rise in the urinary excretion of prolactin, the significance of which at present is obscure, and there was a great increase in the excretion of gonadotrophic hormone due to the urinary spillage of the chorionic gonadotrophin. In all instances, the next menstrual period was delayed significantly, and in only one instance did spontaneous menstruation occur while the medication was being given. The endometrial biopsies and surgical specimens obtained during the administration of chorionic gonadotrophin all showed a definite decidual type of reaction. All of the endometria obtained in the cycle prior to the administration of chorionic gonadotrophin showed typical progestational phase.

Vitamin B₆ deficiency in the Syrian hamster
GREGORY SHWARTZMAN and LOTTE STRAUSS *Division of Bacteriology, Labys of The Mount Sinai Hospital, New York City*. Male weanling Syrian hamsters were maintained on a purified diet containing the essential vitamins and biotin but deficient in vitamin B₆. This led to arrest of growth after a depletion period of 2 to 3 weeks, diminished food and water intake, progressive malnutrition, muscular weakness and changes of the fur. Increased quantities of xanthurenic acid were found in the urine. The deficient animals did not survive beyond 12 to 13 weeks showing loss of fat tissue and marked atrophy of the lymphoid tissues, notably the thymus, even when malnutrition was mild. There was arrest of sexual maturation. Paired controls receiving 50 γ pyridoxine HCl daily showed arrest of growth and atrophy of lymphoid tissues, but failed to develop fur changes, muscular weakness, or cachexia. Controls fed ad libitum and receiving daily 50 γ of pyridoxine HCl showed good growth and nutrition and normal activity. Their fur was normal and there was no atrophy of the lymphoid tissues. Upon treatment of the deficient animals with daily injections of 50 γ of pyridoxine HCl after a depletion period of 9½ weeks, there was in most animals a resumption of appetite and growth, deposition of fat and general return to normal behavior and appearance. Fur changes were repaired within one week of treatment. A single injection of pyridoxine HCl to a deficient animal seemed to bring about similar results, the effect lasting for about two weeks. Although the presence of unsaturated fatty acids in the diet seemed to delay the onset of deficiency symptoms, the addition of corn oil to the diet of animals in an advanced state of depletion did not have any beneficial effect.

Retardation of the reaction time in parathyroidectomized rats CARL C SMITH (by invitation) and HERBERT C STOERK *Merck Inst for Therapeutic*

Research, Rahway, N J. 'Reaction time', the time necessary to elicit a response to a painful stimulus, appears to be a complex sum of events involving perception, conduction along sensory and motor neurons and synaptic transmission. Since a state of hyperexcitability of the motor nerve endings is known to exist in parathyroid insufficiency, it was thought that in parathyroidectomized rats reaction times may be measurably shortened. Contrary to expectation it was found that reaction times were significantly prolonged in parathyroidectomized rats. The method of estimating reaction times was that of D'Amour and Smith in which light from a small bulb is focused by a reflector on the blackened tip of a rat's tail. The reaction times of parathyroidectomized rats, ten days after operation, were 10-50% greater than those of controls. Simultaneous measurements as expected demonstrated increased excitability of motor nerves. The prolonged reaction times could be obtained as soon as two days after parathyroidectomy when Na₂HPO₄ (230 mg/kg) was administered orally. The analgesic effect of methadone and the retardation of reaction time due to parathyroid insufficiency appear to be additive.

Effect of malnutrition on the infection of mice with influenza virus DOUGLAS H SPRUNT *Division of Pathology and Bacteriology, Univ of Tennessee College of Medicine, Memphis, Tenn*. We have previously reported that adult mice, which were fed a diet low in protein but adequate in all other respects, were more resistant to infection with the swine influenza virus than were mice given an adequate diet. The mice were fed the low protein diet for 2 weeks before inoculation with the virus and until the end of the experiment 2 weeks after inoculation. Since this report we have found that this increased resistance to viral infections disappears if the mice are kept on the low protein diet for a longer period of time. It has also been found that the resistance of immature mice cannot be increased by a low protein diet. The immature mice are more susceptible to infection even though they are on the low protein diet. In all these experiments an equal number of mice have been kept without virus in order to see if the malnourished mice are dying of malnutrition. In every instance the diet has proven adequate to support life. At present we do not have sufficient data to explain the above phenomenon but believe it is due to the fact that animals on a low protein diet call upon their reserves of protein and hence are not on a low protein diet until these are depleted. The immature mice we believe are more susceptible because no appreciable reserve exists.

Determination of minimal daily essential amino acid requirements in protein-depleted male albino rats C H STEFFEE (by invitation), R W WISSLER (by invitation), E M HUMPH-

REYS (by invitation), E P BENDITT, R L WOOLRIDGE (by invitation), and P R CANNON *Dept of Pathology, Univ of Chicago, Chicago, Ill* The response of a group of 24 protein-depleted rats fed a relatively complete amino acid ration was used as the standard for determining the quantitative requirements for each of the nine essential amino acids for adequate regain of weight in ten days For this purpose 247 protein-depleted rats were used With different amino acid intakes, weight gains were directly parallel to changes in carcass protein By varying the intake of each amino acid successively, without altering other dietary components, the requirements for each were ascertained These requirements represent the minimal quantity of each essential amino acid which, in conjunction with the remainder of the standard ration, produced weight gains equal to those induced by feeding the complete standard ration Moreover, excellent weight gains followed the feeding of an identical ration, containing only these minimal quantities used have no absolute value, except under these experimental conditions, the proportions of amino acids required in relation to one another may have wide significance For example, the repleting rat utilizes from one to four times the quantities of essential amino acids needed for maintenance The requirements for leucine and lysine are greatest, and these amino acids are found in high concentrations in mammalian muscles It is suggested that the variant results obtained by other investigators with amino acid rations may be due to their use of inadequately proportioned mixtures of amino acids

Influence of nutrition on plasma vitamin A alcohol FREDERICK STEIGMANN, HANS POPPER, HATTIE A DYNIEWICZ (by invitation) and IRENE A MAXWELL (by invitation) *Heiktoen Inst for Medical Research of the Cook County Hospital, Dept. of Pathology, Northwestern Univ Medical School, and Dept of Internal Medicine, Univ of Illinois College of Medicine, Chicago, Ill* The plasma vitamin-A level depends upon endogenous factors like diseases (influencing release of vitamin A from the liver and its intestinal absorption) as well as upon nutritional factors This explains the equivocal correlation between plasma vitamin-A level and nutritional state Recent experiences indicated that the vitamin-A alcohol level responds more readily than that of vitamin-A ester to changing vitamin-A nutrition Therefore, vitamin-A alcohol and ester plasma levels were studied in 19 patients with either conditions without known influence upon vitamin-A metabolism (controls) or with liver diseases They were kept for 1 to 4 weeks on different levels of vitamin-A nutrition (from zero to 20,000 μ) These first periods were alternated with others with increased or reduced vitamin-A intake In controls kept for more than

one week on diets not exceeding 1500 μ vitamin A, the alcohol level dropped, whereas, the esters revealed irregular variations After prolonged periods on low intake, rise of alcohol and ester vitamin A might ensue, possibly as result of release from the liver After complete depletion of over one week, intake of 10,000 μ raised the alcohol level consistently without influence upon esters After a pre-period of 1500 μ intake, 3000 μ caused a rise in half the cases Secondary depletion and repletion periods of 1 week duration revealed less consistent results The curves in patients with liver diseases were erratic Serial follow up of the plasma vitamin-A alcohol level may, therefore, in normals with certain reservations mirror the status of vitamin A nutrition and possibly permit estimation of the human vitamin A requirement

Studies of leukocyte production and distribution factors in plasma and in leukocytes BERNHARD STEINBERG and RUTH A MARTIN (by invitation) *Toledo Hospital Institute of Medical Research, Toledo, Ohio* One of the significant questions in hematology concerns the mechanism which maintains the solid constituents of the blood at a constant definite level Our investigations (*Proc Soc Exp Biol & Med* 56 50-52, 1944, *J Immun* 51 421-426, 1945, 52 71-75, 1946, 53 137-141, 1946) of the immunochemical characteristics of various types of leukocytes of variable ages and physical states suggested the possibility of the presence of regulating substances within the cells Normal and leukemic plasma with and without contact with normal or leukemic cells as well as leukocytes only were injected into rabbits The animals were either normal or prepared by injections of benzene and extracts acting on the marrow Studies were made of marrow, other organs and of the peripheral cell content The tissues as well as the blood gave indications that intact leukocytes contain a substance which is secreted into plasma and which acts on the marrow to inhibit the expulsion of cells Degenerating leukocytes, on the other hand, secrete a substance which accelerates cell expulsion from the marrow Effect of various temperatures on the active substances were determined There is suggestive evidence that these substances are of the nature of enzymes Correlations were made with other materials such as milk, which apparently induce a change in the peripheral leukocyte picture by an increase in cell expulsion

Influence of chorionic gonadotrophin on the hilus cells of the human ovary WILLIAM H STERNBERG (by invitation), ALBERT SEGALOFF, and CORNELIA J GASKILL (by invitation) *Depts of Pathology and Medicine, Tulane Univ, the Alton Ochsner Medical Foundation and the Charity Hospital, New Orleans, La* The hilus and mesovarium of the human ovary normally contain nests of cells morphologically identical with Leydig cells They

contain lipids, acidophilic granules, lipochrome pigment and crystalloids of Reinke as do the interstitial cells of the testis. They are intimately associated with non-myelinated nerves and vascular spaces. During pregnancy and at the menopause they are especially conspicuous. We have recently studied 3 instances of tumor and 3 of hyperplasia of these cells all associated with masculinizing syndromes. Five regularly menstruating patients were treated with chorionic gonadotrophin and their ovaries examined histologically. The dosage was 10,000 u of chorionic gonadotrophin daily to each for periods of 12 to 19 days following ovulation. This dosage usually delays menstruation and produces a decidual reaction. Morphologic changes were noted in the ovarian hilus cells. The cells were present in larger than average numbers, and the cytoplasm more granular and acidophilic. In one case mitoses were present, although mitoses are not ordinarily seen either in hilus cells or in testicular Leydig cells. In 3 cases focal areas of degeneration were noted, including pyknosis, clumping of nuclei, and loss of cell outlines. Similar changes were noted in a case of chorionepithelioma of the uterus, and a teratoma of the ovary in which urinary gonadotrophin was elevated. The findings suggest that ovarian hilus cells are responsive to chorionic gonadotrophin. It is likely that they are one of the sources of androgen in the human female.

Mechanical and osmotic fragility in relation to age of dog erythrocytes tagged with radio-iron. W B STEWART, J M STEWART, M J Izzo and L E YOUNG (introduced by C L YULE) *Depts of Pathology and Medicine, Univ of Rochester School of Medicine and Dentistry, Rochester, N Y*. The mechanical and osmotic fragilities of dog erythrocytes of known age tagged with radio active iron were measured and compared with the fragilities of the total cell population. Under the stimulation of severe bleeding prior to intravenous administration of a small dose of radio-iron, the radio activity could be confined to a group of cells whose age was known within reasonable limits. As the cells matured and aged, measurements were made of their abilities to resist destruction by rotating glass beads and to resist hemolysis in hypotonic solutions of sodium chloride. Hemolysis of the total cell population was determined by conventional methods and hemolysis of the tagged cells by measurements of radioactivity. Comparison of the figures obtained revealed that cells up to 3-6 weeks of age were more resistant to mechanical trauma than the total cell population. The 2 fragility measurements then became almost identical until 12-15 weeks of age when the tagged cells were found to become increasingly fragile. The ratios then reversed after the tagged cells reached the end of their life span. A transient drop was noted in the total circulating radio-iron at this

point corresponding to a life span of about 17 weeks for the tagged cells. The osmotic fragility of the tagged cells was considerably greater than that of the total cell population for the first week, confirming results obtained earlier by Cruz, Hahn, Bale, and Balfour (*Am J Med Sci* 202, 157, 1941). Data for the older cells were inconclusive.

Parathormone and renal reabsorption of phosphate. HERBERT C STOERK and ROBERT H SILBER *Merck Inst for Therapeutic Research, Rahway, N J*. Although it has been established that parathormone (PTH) activity is not dependent upon renal function, evidence has been presented both for and against an effect of PTH upon the reabsorption of phosphate by the renal tubules. In the present experiments, the renal excretion of phosphate during a 5-hour period was determined in parathyroidectomized and in intact rats after administration of graded amounts of phosphate (0, 4 and 8 mg of P as Na_2HPO_4) and parathyroid extract (5-160 u , Lilly). In intact rats it was found that urinary phosphate excretion was not altered by the injection of 5 to 160 u of parathyroid extract. In parathyroidectomized rats the renal excretion of phosphate, but not of creatinine, was greatly suppressed. This defect was corrected by the administration of 20 u and no additional effect upon phosphate excretion was obtained with larger amounts of parathyroid extract (up to 160 u). In parathyroidectomized rats, injected with 20 or more u of extract, as well as in intact rats, an increased intake of phosphate led to an increase in urinary phosphate. It therefore appears that excessive amounts of parathyroid extract (more than 20 u per rat) exert no additional effect on the urinary excretion of phosphate. Thus the influence of PTH upon tubular reabsorption of phosphate is essentially an 'all or none' effect and can not be demonstrated in the presence of adequately functioning parathyroid tissue.

Eclampsia-like condition in pregnant rats injected with progesterone. A SYMEONIDIS (introduced by H L STEWART) *National Cancer Institute, Bethesda, Md*. Pregnant rats (24, strain M-520) injected with 20 mg of progesterone, intramuscularly (5 mg every day) in late pregnancy became ill. Some of them aborted dead embryos following which they recovered. In other rats the embryos were absorbed. Approximately 40% of the treated animals died. The liver and the kidney showed striking gross and microscopic lesions resembling those of eclampsia. Elevation of the non-protein nitrogen of the blood and albuminuria were found. The blood pressure was significantly elevated in 5 animals examined. Pregnant females receiving the same treatment prior to the 15th day of pregnancy and virgin tested rats failed to show any changes.

Relations between volumes of closed hypo-

thermal cerebral lesions and symptoms in rabbits
C BRUCE TAYLOR (by invitation), GEORGE M HASS and JOHN E MALONEY (by invitation) *Rush Dept of Pathology, Presbyterian Hospital, and Dept of Pathology, Univ of Illinois College of Medicine, Chicago, Ill* Acute closed cerebral lesions characterized by hemorrhage, necrosis and progressive edema were produced hypothermally in rabbits without interrupting continuity of the calvarium or introducing variables incidental to mechanical trauma The dimensions and locations of lesions were controlled so that they could be reproduced in successive animals Although hemorrhage, edema and necrosis varied slightly in lesions otherwise identical, the variations were restricted to discrete volumes of injury When unilateral or bilateral lesions occupied less than 9.4 volumes % of the brain, symptoms were negligible When lesions occupied 9.4 to 18.5 volumes % of the brain, severe symptoms developed in many animals The minimum lethal volume of cerebral damage in 50 % of more than one hundred animals was 14.3% of the volume of the brain Severe clinical courses with an average postoperative duration of 7 hours and fatal termination always occurred when lesions occupied more than 18.5 volumes % of the brain Most animals that died had a normal postoperative period of behavior Secondary lapse into stupor was a dependable indication of coma and eventual death within 24 hours after operation These data indicate that a quantitative experimental approach to treatment of acute expanding closed intracerebral lesions characterized by local necrosis, hemorrhage and edema can now be made The postoperative duration of life can be predicted from the magnitude of lesions produced and this duration is sufficient to permit evaluation of most therapeutic methods, now used empirically in treatment of similar lesions in humans

Proteinuria in dogs ROGER TERRY (introduced by G H WHIPPLE) *Dept of Pathology, School of Medicine and Dentistry, Univ of Rochester, Rochester, N Y* If homologous plasma is given parenterally to normal dogs for a sufficient period, proteinuria develops Additional experiments to those previously reported have been designed to help elucidate the mechanism of this proteinuria Circulating plasma protein levels must be elevated above a critical 'threshold', and there appears to be a lag period between the development of hyperproteinemia and the onset of conspicuous proteinuria This suggests that the 'threshold' for plasma protein molecules may be related to a large accumulation of these protein molecules within the renal tubule cells

Actions of 4-amino-pteroylglutamic acid in dogs with special reference to hematopoiesis J B THIERSCH and F S PHILIPS (introduced by C P RHOADS) *Division of Experimental Chemotherapy,*

Sloan-Kettering Inst for Cancer Research, New York City Accepting 4-amino-pteroylglutamic acid as a folic acid antagonist from studies in rats (Philips and Thiersch, *J Pharm Exper Therap*, *in press*) its actions in dogs were examined Acutely toxic doses proved fatal within 3 to 4 days while daily doses (0.05 to 0.10 mg/kg) were fatal to approximately 50% of animals within 10 days Signs of intoxication included occasional emesis, anorexia, losses in weight and electrolyte, hemorrhagic diarrhea, leucopenia, hemoconcentration, and terminal collapse In acutely intoxicated animals serial aspirations revealed rapid degeneration of bone marrow Within 24 hours abnormal erythroid elements could be found including nuclear remnants, pathologic mitoses, and megaloblasts After 96 hours erythroid elements were almost absent Simultaneously, myeloid elements and megakaryocytes became decreased in number Pathologic metamyelocytes and myelocytes appeared In chronic intoxication, similar but less rapid degeneration of bone marrow occurred although megaloblasts were not found in all animals In poisoned dogs lymphopoiesis was less affected, by comparison, than was either erythro- or myelopoiesis Edema of intestinal mucosa and desquamating colitis with hemorrhage were present in all dogs

Thermostable inhibition of bacterial hyaluronidases by serum of normal human beings ROBERT T THOMPSON and FRANCES E MOSES (introduced by M A BLANKENHORN) *Dept of Internal Medicine, College of Medicine, Univ of Cincinnati, Cincinnati, Ohio* This study investigated the inhibition of similar test strengths of hyaluronidases in culture filtrates of Type 3 Pneumococcus, hemolytic *Staphylococcus aureus*, *Clostridium perfringens*, beta hemolytic Streptococcus (group A), and purified bovine testicular hyaluronidase by the serum of 50 normal human beings who were between 20 and 40 years of age Hyaluronidase inhibition was measured by a mucoprotein clot prevention test using egg albumin as the protein component of the substrate Each serum was tested immediately as it was removed from the clot, and again after it had been heated at 56°C for 30 minutes Results tabulated below reveal thermostable inhibition of Pneumococcus and Staphylococcus hyaluronidases by normal serum

Hyaluronidase tested	No sera tested	Inhibiting sera	Thermostable inhibiting sera
Pneumococcus	50	47	45
Staphylococcus	49	23	19
Cl Perfringens	50	16	10
Streptococcus	50	12	7
Testicular	48	46	2

Tests upon consecutive daily sera of 1 person revealed consistent inhibition of the pneumococ-

cus, staphylococcus, and testicular hyaluronidases. However, there was fluctuation in the inhibition of the *Streptococcus* and *Cl. perfringens* hyaluronidases, so that results of the inhibition of these 2 enzymes tabulated above are of undetermined significance. The inhibition of testicular hyaluronidase which disappeared after heating could be restored by the addition of complement to the heated serum. The complement used was a 1:30 dilution of normal guinea pig serum, which itself did not inhibit the test strength of hyaluronidase.

Association of lymphoid elements with cancer cells undergoing distinctive necrobiosis in resistant and immune hosts. HELENE W. TOOLAN (by invitation) and JOHN G. KIDD, *Dept. of Pathology, The New York Hospital—Cornell Medical Center, New York City*. Regression of C3H cancers in 'A' mice proceeds inwards from the periphery, the tumor cells in groups in the centermost parts of the regressing nodules, and often those surrounding blood vessels, continuing to undergo mitosis and showing no signs of injury until their more peripheral fellows are overcome. Scrutiny of the cells about the edges of the regressing tumors made it plain that they do not die 'en masse', but instead succumb one by one, manifesting as they do so a distinctive type of necrobiosis. This is characterized by a gradual but progressive shrinkage of the cell with intensified basophilism of its nuclear and cytoplasmic constituents, and often with the accumulation of fluid around it, eventually with further shrinkage the nuclear membrane breaks down and the condensed and darkly-staining cellular remains dwindle and disappear without the intervention of phagocytes. The tumor cells never exhibit the necrobiotic changes just described until lymphoid elements provided by the host accumulate in force about them and attach themselves to first one and then another of the outlying cancer cells, adhering closely to them and often curving like crescents about their rims as they shrink, while adjacent tumor cells without attached lymphocytes remain unaltered. Further studies showed that cancer cells of both types proliferate for a short time when implanted in 'A' mice in which they had previously grown and regressed, but with the accelerated arrival of lymphoid elements they are promptly overcome as described above.

Passive transfer of age resistance to an avian malaria parasite. WILLIAM TRAGER and R. BARCLAY MCGHEE (by invitation), *Dept. of Animal and Plant Pathology, Rockefeller Institute for Medical Research, Princeton, N. J.* If young chicks are inoculated intravenously with the erythrocytic stages of *Plasmodium lophurae* they undergo an acute, severe infection. If adult chickens are similarly inoculated, few of them exhibit any appreciable parasitemia. It has now been found that the

plasma of adult chickens contains a material which when injected into young chicks infected with *P. lophurae* is capable of reducing the extent of multiplication of the parasites. One-week old chicks were given a dosage of *P. lophurae* sufficient to produce an initial parasite count of 1 to 2 parasites per 100 red cells. They were then given an intravenous injection once daily for 2 to 4 days of 3 ml. of either heparinized adult chicken plasma, buffered saline (pH 7.4) or 6% bovine albumen in buffered saline. The chicks receiving adult chicken plasma consistently developed less severe infections than those receiving saline or bovine albumen. For example, in one experiment the averages of the peak parasite numbers were, as parasites per 100 red cells, 102 for the group receiving albumen, 47 for the group receiving hen plasma and 102 for the group receiving saline. The activity of the hen plasma was not destroyed by heating it for one half hour at 56°C.

Radioresistance and radiosensitivity of swine exposed to atomic bomb radiation. JOHN L. TULLIS (introduced by F. S. ROBSCHT-ROBBINS), *Commander, MC, U. S. Navy*. Irradiation of the total body with an atomic bomb source affords a fairly accurate method of studying the differences in radiosensitivity of tissues. The variables introduced by the body thickness of swine and the differences in specific density of the tissues are minimized by the use of atomic bomb radiation, but they are by no means eliminated. The most radiosensitive tissues in swine are the lymphoid elements, the bone marrow, the gonads and the intestinal epithelium. It is significant and interesting that the reticular cells (the stem cells) of the lymph nodules and bone marrow, the indifferent cells (the stem cells) of the immature testis, the primordial ova, macrophages and plasma cells are relatively radioresistant. That is to say, doses of total body irradiation from an atomic bomb, or other source of penetrating ionizing radiations, sufficient to kill swine often cause no morphologic alteration in the cells listed. If treatment during the acute phase of the injury is successful in maintaining life, there is histologic evidence that regeneration of radiosensitive cells can be accomplished by certain radioresistant apparently-uninjured stem cells.

Intradermal vaccination with infectious psittacosis virus: pathological changes. JOSEPH VICTOR and JOHN C. WAGNER (by invitation), *Biological Dept., Chemical Corps, Camp Detrick, Frederick, Md.* Injection of psittacosis virus intramuscularly in monkeys (Rivers and Schwenker, *J. Exp. Med.* 60:211, 1934) and intradermally in guinea pigs has produced resistance to respiratory challenge. Pathological effects of intradermal injection of guinea pigs of strain 6BC grown in chick embryo yolk sac (6BCYS) were studied at intervals during

5 weeks after injection. Distribution of virus in tissues of these animals is reported elsewhere. The infectious material produced acute inflammation at the injected site. The skin lesion later became granulomatous with fibroblast and giant cell formation after 3 weeks. Ceroid pigment occurred within histocytes and giant cells 3 weeks after injection of 6BCYS. Ceroid was identified from its fluorescence in U-V light, acid fastness with carbol-fuchsin and its affinity for basic and lipophil dyes. Regional lymph nodes became hyperplastic and hypertrophied reaching maximum size at about 2 weeks. Ceroid appeared in these nodes at 5 weeks and seemed to have migrated from the skin lesion. Liver contained midzonal areas of focal necrosis for 2 weeks. After 3 weeks, collections of histocytes replaced the midzonal necrosis. Control animals injected intradermally with normal chick embryo yolk sac or formalinized yolk sac infected with 6BC revealed no changes comparable to those treated with infectious virus. Lesions in skin, regional lymph node and liver persisted longer than detectable virus. No virus was found in livers with focal necrosis.

Comparison of two types of experimental ascites in the dog. WADE VOLWILER (by invitation), JESSE L. BOLLMAN and JOHN H. GRINDLAY *Mayo Foundation, Rochester, Minn.* Ascites in the dog has been regularly produced by 1) chronic passive congestion of the liver from the application of a cellophane band to the thoracic inferior vena cava and 2) plasmapheresis following the application of a cellophane band to the abdominal inferior vena cava and portal vein. Although portal and inferior caval venous pressures are elevated to the same moderate degree in both types of preparations, the character of the ascites is markedly different. The ascites accompanying Preparation 1 is rapidly progressive, high in protein content, and regularly associated with marked engorgement of the extrahepatic liver lymphatics, whereas the abdominal fluid appearing in Preparation 2 is less extensive and difficult to maintain, low in protein content and without associated lymphatic enlargement. Evans blue dye injected intravenously into dogs of Preparation 1 is found in the ascites in one hour, the dye does not appear in the abdominal fluid of Preparation 2 in detectable amounts in 48 hours. Assays for antidiuretic substances in the urine concentrates of dogs of Preparation 1 have been made using male rats having suprapubic cystotomies for individual urine collections. Since previous studies have shown that the protein content of hepatic lymph is approximately $\frac{1}{3}$ that of plasma and that the rate of flow of liver lymph is markedly increased from hepatic congestion, it is suggested that increased transudation of fluid through the dilated extra-hepatic liver lymphatics

contributes importantly to the formation of the ascites associated with hepatovenous congestion.

Intradermal vaccination with infectious psittacosis virus. **virus distribution** JOHN C. WAGNER (by invitation) and JOSEPH VICTOR *Biological Dept., Chemical Corps, Camp Detrick, Frederick, Md.* Production of immunity to psittacosis virus introduced into respiratory tract has been reported in monkeys by Rivers and Schwentker, following intramuscular inoculation of infectious virus. Similar observations were made following intradermal administration of psittacosis virus, in guinea pigs. This study attempts to elucidate factors concerning this resistance. Tissues of guinea pigs injected with psittacosis virus were studied for distribution of virus and pathological changes. Psittacosis virus, 6BC strain, cultivated in chick embryo yolk sac, was inoculated intradermally in a concentration of 300,000 egg LD₅₀ in 0.5 ml broth suspension. Autopsies were performed 1, 2, 3, 6, 9, 14, 21 and 35 days thereafter. Tissues were tested as 10% suspensions in nutrient broth by intracerebral inoculation of mice. Presence of virus in guinea pigs was established by demonstration of elementary bodies in smear preparations of brains from injected mice that died. Evidence obtained indicated that treated guinea pigs harbored virus for 6 days at site of inoculation, for 14 days in regional lymph nodes and sporadically for 9 days in the liver. Spleen suspensions yielded virus on the first day in only 1 of 3 animals. No virus was detected in suspensions of contralateral lymph nodes, whole blood, heart, lung or kidney. Virus distribution data indicated that psittacosis virus inoculated intradermally migrated from site of injection to regional lymphatics and thence to internal organs. Pathologic studies confirmed this. Resistance to respiratory infection occurred in the absence of any demonstrable virus or lung lesions.

Effect of renal ischemia on the production of nephrosis in jaundiced rabbits. W. B. WARTMAN, J. M. TUCKER (by invitation), A. P. RUSTERHOLZ (by invitation) and R. JENNINGS (by invitation) *Dept. of Pathology, Northwestern Univ. Medical School, Chicago, Ill.* The purpose of these experiments was to test the assumption that the presence of previous kidney damage might be a factor in the development of bile nephrosis. Using rabbits, one kidney was damaged by temporarily occluding the right renal artery and vein for 15 to 20 minutes, and the common bile duct was divided. Lesions developed in the kidneys of approximately 45% of animals after 3 days. They were chiefly in the cortex of the kidneys and consisted of dilatation of both proximal and distal segments of the tubules, flattening, degeneration and necrosis of the lining epithelium and numerous reddish brown, granular, heme casts. There were no clinical evidences of kidney disease. No changes were dis-

covered in rabbits in which only the common bile duct was cut, nor in animals in which only the right renal artery and vein were obstructed, nor did rabbits in which the common bile duct and right renal pedicle were dissected out but not otherwise manipulated show changes in the kidney. Prolonged and severe restriction of water intake had no demonstrable influence on the development of the nephrosis. It is concluded that under the conditions of these experiments, a peculiar type of bilateral nephrosis may be produced in rabbits by a combination of jaundice and temporary, unilateral, renal ischemia, and that it is produced neither by jaundice alone nor renal ischemia alone. Restriction of fluid had no effect upon the development of the lesion.

Bactericidal action of dog blood against *Br suis*
E. BUIST WELLS (by invitation), JEAN CLEMENTS (by invitation), ABRAHAM D. POLLACK (by invitation) and JOSEPH VICTOR, *Biological Dept., Chemical Corps, Camp Detrick, Frederick, Md.* Irwin et al (*J. Inf. Dis.* 58: 15-22, 1936) have reported that bovine plasma had greater bactericidal activity than whole blood against *Br suis* and *Br abortus*. The present study indicated that in the dog whole blood possessed great bactericidal activity against *Br suis* whereas plasma had none. A standardized number of organisms of a virulent strain was mixed with either normal dog blood, red blood cells, buffy coat or plasma. Mixtures were agitated in rotating tubes. Bacterial numbers were counted by dilution and plating. The influence on bactericidal action of blood of citrate, heparin, temperature, time of mixing, volume of blood and interval between addition of fresh blood was studied. Citrate suppressed bactericidal activity of blood whereas heparin did not. Bactericidal activity of blood was the same both at room temperatures and at 37°C after 2 hours. In contrast, after 4 hours bacterial destruction was greater at 37°C than at room temperatures. Repeated additions up to 4 hours of fresh blood to the mixtures did not influence bactericidal action. Activity of buffy coat was similar to that of whole blood. Plasma was inactive. Blood from which almost all leukocytes had been removed by centrifugation possessed much less activity than whole blood. It appeared that bactericidal power of dog blood for *Br suis* depended on the presence of leukocytes.

Clearance of rose bengal by livers of normal and carbon tetrachloride-treated mice
W. LANE WILLIAMS, *Dept. of Anatomy, Univ. of Minnesota, Minneapolis, Minn.* Livers of untreated mice were cleared of rose bengal (intraperitoneal, 0.4 cc, as a 1% saline solution 25 gm body weight) within 4 to 6 hours post injection. Twenty-four hours after treatment with 0.4 cc of CCl₄ (subcutaneously in mineral oil) total clearance time was 9 to 11 hours, at 48 hours, 11 to 14 hours. These livers showed

typical centrilobular damage. Nine days subsequent to a single injection of 0.01 cc of CCl₄, livers showed no histological evidence of parenchymal damage but dye clearance time was 8 to 9 hours. One day after injection of the larger amount of hydrocarbon all parenchymal cells (including peripheral ones) were more deeply stained (cytoplasm) than equivalent cells in livers of untreated animals. Greatest amount of dye was in centrilobular cells of injured livers. Although these central zones eventually showed necrosis the deeply stained centrilobular cells were still able to excrete dye 48 to 60 hours after injection of CCl₄. Intracytoplasmic rose bengal is difficult to determine in cytological studies because of its light pink color. However, the presence of a greater intracytoplasmic concentration of dye transiently 'labels' and differentiates damaged parenchymal cells. All such cells were free of dye within 8 to 14 hours after injection. In ultraviolet light 10μ paraffin sections of normal livers showed a faint yellow fluorescence during the period of greatest dye content. In CCl₄-damaged livers a definite orange fluorescence was observed during the interval of maximum dye content.

Vitamin deficiency and protein synthesis with special reference to riboflavin-protein interrelationships
ROBERT W. WISSLER (by invitation), EARL P. BENDITT, C. HAROLD STEFFEE (by invitation) and ROBERT L. WOOLRIDGE (by invitation), *Dept. of Pathology, Univ. of Chicago, Chicago, Ill.* The omission of all vitamins from the diet of normal young adult albino rats produced little change in weight gain or diet consumption for about 30 days. Under similar conditions protein-depleted rats showed poor diet consumption and weight loss in 2 or 3 days after being shifted to a low vitamin ration adequate in protein. When each vitamin was removed singly from protein-repletion rations, groups of protein-deficient rats displayed marked reduction in diet consumption and weight gain only when the diets were devoid of riboflavin or thiamin. Riboflavin deficiency usually began to become apparent in 3 or 4 days, thiamin in 7 to 10 days. Antibody production was markedly reduced in the riboflavin-deficient rats. Pair-feeding experiments revealed that the poor weight gains shown by the protein-depleted rats repleting on riboflavin-deficient diets were not the result of inanition alone. Analyses of the various tissue compartments revealed that the smaller weight gains of these riboflavin-deficient rats were the result of interference with protein synthesis as well as fat storage. Liver and carcass analyses indicated that riboflavin storage is decreased in the protein-depleted rats despite adequate riboflavin intake. Succinic dehydrogenase and other enzymic activity was reduced in the livers of protein-depleted animals and remained low in those repleting without

dietary riboflavin Protein-depletion interferes with enzyme activity and riboflavin storage possibly by limiting available protein prosthetic groups

Response of the rachitic metaphysis in the rat to excessive administration of vitamin A S B WOLBACH and CHARLOTTE L MADDOCK (by invitation) *Division of Nutritional Research, Children's Hospital, Boston, Mass* It has been shown (*Proc Inst of Medicine of Chicago* 16 1946, and *J Bone and Joint Surg* 29 171, 1947) that in the growing young animal the administration of excessive amounts of vitamin A accelerates growth and maturation of epiphyseal cartilage cells and the remodelling sequences of the bones of the skeleton This has been demonstrated for the rat, mouse, guinea pig and dog It causes rapid consumption of the epiphyseal cartilage and, in appropriate species, premature closure of epiphyses, also excessive rapidity of remodelling processes in regions which undergo remodelling in normal growth The present communication is for the purpose of describing effects upon the accumulated cartilage in rachitic metaphysis which results from failure of cartilage cells to mature The rachitogenic diet employed was composed with the advice of Dr Otto A Bessey and contains all essential materials with the exception of adequate phosphorus content Under the influence of excessive vitamin A administration there is rapid repair of rachitic lesions, including resumption of normal epiphyseal cartilage cell cytomorphosis and calcification of cartilage matrix and osteoid Partial to complete closure of the distal, femoral and proximal tibial epiphyses takes place in spite of the fact that in these locations epiphyses remain open for most of the lifetime of the rat Acceleration of remodelling

sequences occurs as in rats upon normal diets and in conformity with normal growth patterns Our results support the idea that epiphyseal cartilage cell sequences are influenced by a factor other than those concerned in calcification of matrices

Effects of protein deficiency upon natural and acquired immunity to Friedlander's bacillus ROBERT L WOOLRIDGE (introduced by PAUL R CANNON) *Dept of Pathology, Univ of Chicago, Chicago, Ill* The effects of protein depletion on natural and acquired immunity against infection with Friedlander's bacillus were studied in adult male albino rats following intranasal or intratracheal introduction of a standardized inoculum Forty-one markedly protein-depleted rats showed a significantly lower agglutinin response on the 6th and 14th days after antigenic stimulation, with a concomitantly lower survival rate, than did 40 well-nourished controls When the animals were sacrificed the controls had only a few focal pulmonary abscesses whereas the protein-depleted rats had many large chronic pulmonary abscesses which showed evidence of progressive enlargement with approximately 50% of each lung consolidated Marked protein depletion also lowered natural resistance in that an intratracheal inoculum which was sublethal for the control animals killed all of the protein-depleted rats within 54 hours, with an associated septicemia Histological studies revealed marked differences in the cellular response and degree of phagocytosis For example, in the protein-depleted rats the ability to circumscribe the infection and repair the damaged tissue was definitely impaired whereas the phagocytic ability of the control animals during the early stage of the infection was adequate to protect them until acquired immunity was developed and the infection localized

AMERICAN INSTITUTE OF NUTRITION

Thirteenth Annual Meeting

DETROIT, MICHIGAN, April 18-22, 1949

(For possible corrections in any of the following abstracts see the June issue)

Leucine content and utilization of amino acid mixtures JOSEPH T ANDERSON (by invitation) and E S NASSET *Dept of Physiology and Vital Economics, Univ of Rochester School of Medicine and Dentistry, Rochester, N Y* The utilization of the N of amino acid mixtures in the adult rat was investigated by the method previously described (Anderson and Nasset, *J Nutrition* 36 703, 1948) in which a 'complete' amino acid mixture simulating egg protein is compared with a mixture in which a portion of one of the essential amino acids has been replaced by an isonitrogenous amount of of glutamic acid Reduction of L-leucine to 21.1 mg leucine N/gm total N, which is $\frac{1}{3}$ the value in the 'complete' amino acid mixture, caused a significant decrease in the utilization of the dietary N as indicated by a decrease in N balance index and an increase in N requirement for equilibrium Further reduction of L-leucine by one-half caused a further decrease in N utilization but not so great as would be predicted from the theory that N retention is limited by the supply of limiting essential amino acid Substitution of an equal quantity of DL-leucine for the L-leucine (21.1 mg leucine N/gm total N) resulted in no significant reduction in N utilization Apparently about $\frac{1}{3}$ the maintenance requirement of L-leucine in the rat can be filled by D-leucine

Ammonium persulfate as a flour maturing agent AARON ARNOLD and FRANS C GOBLE (by invitation) *Sterling-Winthrop Research Inst, Rensselaer, N Y* The need for chemical agents for rapidly maturing flour is well established and accepted Nitrogen trichloride, which has been used extensively for this purpose, is no longer acceptable in view of Mellanby's findings of deleterious effects in laboratory animals fed flour thus treated This fact has focussed attention on the suitability of alternative agents Ammonium persulfate has been known for some time to be an effective flour maturing agent, and, in fact, is used extensively abroad, this report presents data obtained in feeding trials of this compound with rats and dogs In chronic experiments, rats were fed diets high in flour or air-dried bread made from persulfate treated flour The levels of treatment were 0.02 and 0.1%, i.e., levels considerably in excess of commercial requirements The rats fed the treated flours or breads

showed no adverse effects The effects were judged on the basis of growth and reproduction performance and histological examination of representative tissues of first and second generation rats sacrificed after 6 months on test Dogs fed ammonium persulfate treated flour not only did not develop the running fits syndrome but were cured of running fits when transferred from a diet containing nitrogen trichloride treated flour to one containing persulfate treated flour As in the case of the rat feeding trials, no adverse effects could be detected in dogs fed flour treated with 0.15% persulfate as compared with dogs fed untreated flour The effects were judged from weight records, kidney and liver function tests, and histological examination of representative tissues after 5 months' feeding Ammonium persulfate appears to be suitable from all view points for use as a flour maturing agent

Effect of diet on treatment of parathyroidectomized dogs AARON ARNOLD *Sterling-Winthrop Research Inst, Rensselaer, N Y* It has been well demonstrated that vitamin D and dihydrotachysterol will substitute for parathyroid hormone in parathyroidectomized dogs However there is a disagreement as to the amounts of the calcemic steroids required For 16 months, 2 adult thyro-parathyroidectomized dogs were fed a mixture of 2 parts fresh ground meat and 1 part cereal diet (in percentage: corn 26, wheat 26, skim milk powder 24, linseed meal 8, casein 4, peanut oil 4, yeast 3, alfalfa meal 3, bone meal 1, CaCO_3 0.5, and NaCl 0.5) The composite diet supplied 0.58% Ca and 0.73% P The dogs were given, in addition, 0.3 gm thyroid powder daily and the usual vitamin supplements orally once weekly In agreement with the results of McChesney and Giacomino (*J Clin Invest* 24 680, 1945), the dogs were observed to require approximately 0.0875 mg of dihydrotachysterol or 0.2 mg of calciferol daily per 10 kg dog This amount of calciferol was about 200-fold greater than that found necessary by Kozelka *et al* (*J Biol Chem* 100 715, 1933) The requirement does not appear to be correlated with the dietary calcium and phosphorus but may be related to the general nature of the diet Specifically, dogs fed a diet with a substantial proportion of fresh meat require much greater quantities of vitamin D or dihydrotachysterol than do dogs fed diets com.

posed largely of cereal grains. This suggestion may apply also to the marked difference in the amount of vitamin D required to prevent the onset of rickets in dogs as reported by the Fleischmann Laboratories (unpublished data, 1936) and by Arnold and Elvehjem (*J Am Vet Med Assoc* 95:187, 1939).

Influence of heredity on the crude protein and carotene contents of corn L W AURAND (by invitation) and R C MILLER *Dept of Agricultural and Biological Chemistry, Pennsylvania State College, Penna*. Crude protein and carotene values have been determined on corn produced in 3 different series of experiments, each of which had all possible single cross combinations of 10 different inbred lines of corn. Each experiment was completely replicated on at least 3 experimental plots which had the same fertilizer treatment. Separate samples of corn from each single cross combination on each plot were analyzed for protein and carotene, and average values were computed from all of the individual data for each single cross on each experiment. Significant differences in the protein and carotene values for single crosses definitely reflected the influence of the breeding of the inbred lines on the resulting single crosses. The latter had crude protein contents ranging from 7.95 to 12.58% and carotene contents ranging from 0.53 to 1.95 mg/lb, all values being expressed on the basis of 15.5% moisture content of the corn. The definite influence of inbred lines was shown in characteristically high or low crude protein and carotene contents of the resulting single cross combinations. Although these relationships were true for both crude protein and for carotene there was no correlation between the crude protein and carotene contents of corn tested. The results show a definite influence of heredity on the carotene and crude protein content of corn and point the way for improvement of the nutritive value of corn by the plant breeder.

Nutritional requirements of men living under survival conditions in cold weather C G BLY (by invitation), R E JOHNSON and C F CONSO LAZIO (by invitation) *U S Army Medical Nutrition Lab, Chicago, Ill*. Balance studies were conducted when 32 volunteers, fully acclimatized to Florida winter conditions and unaccustomed to cold weather and its hardships were flown in January from Florida (mean temperature +57°F) without layover to Manitoba, Canada. On arrival they were placed in a field survival situation for 12 days (mean temperature -3°F), where they lived in one of four segregated areas, 8 men per group. The 4 group rations (per man per day) contained 1100 Cal (low calorie control), 1650 Cal, 1940 Cal, 4850 Cal (high calorie control). All urine and feces were collected daily. From analytical data on these, together with analytical data on all

foods and fluids consumed, nutrient balances were computed. For these young men, well outfitted against the cold, with adequate clothing, fuel, and tentage, doing no physical work other than necessary to keep themselves comfortable, nutrient balance could be maintained for 12 days by palatable rations supplying daily for an average 70 kg man 3400 Calories, 2.7 liters water, including beverage, food, and metabolic water, 50 gm protein, mostly animal, 135 gm fat, 400 gm carbohydrate, 1.1 gm calcium, 1 gm phosphorus, 100 mEq sodium, 85 mEq chloride, 20 mEq potassium. These estimates are not applicable for men required to perform any hard physical work.

Animal protein factor and growth of mice fed diets containing succinylsulfathiazole D K BOSSHARDT, J W HUFF (by invitation), WINIFRED J PAUL (by invitation) and R H BARNES *Dept of Biochemistry, Medical Research Division, Sharp and Dohme, Inc, Glenolden, Penna*. The addition of 2% succinylsulfathiazole to purified diets fed to mice caused a growth retardation that was not corrected by the feeding of biotin and pteroylglutamic acid nor by supplements of dehydrated, defatted whole liver. When, however, the biotin, pteroylglutamic acid, and liver were fed together growth rates were obtained comparable with those of mice fed a succinylsulfathiazole-free diet containing liver. Liver has been shown to contain a factor, or factors, referred to as the animal protein factor that is necessary for growth. The results of Ott *et al* (*J Biol Chem* 174:1047, 1948) suggest that vitamin B₁₂ would replace liver in the diet of succinylsulfathiazole-fed mice. The vitamin B₁₂ concentrate was prepared from liver and was found by microbiological assay, using *Lactobacillus leichmannii*, to contain approximately 1% vitamin B₁₂. A vitamin B₁₂ concentrate supplied by the Merck Laboratories was used as a standard. This preparation when administered to iodinated casein-fed mice (Bosshardt *et al* *J Nut*, in press) gave a maximum growth response with a daily intraperitoneal dosage of 0.5 µg. The vitamin B₁₂ concentrate administered by intraperitoneal injection at a level of 1 µg/day to mice fed a diet containing biotin, pteroylglutamic acid, and succinylsulfathiazole produced a marked growth response. However, the growth response did not appear to be as great as that obtained with crude liver.

Riboflavin and nitrogen metabolism of 6 women with active tuberculosis WILMA D BREWER (by invitation), HELEN L TOBEY (by invitation) and MARGARET A OHLSON *Dept of Foods and Nutrition, School of Home Economics, Michigan State College, East Lansing, Mich*. The riboflavin and nitrogen metabolism of 6 women with moderately advanced, active tuberculosis was studied. The subjects were non-ambulatory patients of the county sanatorium and the regular hospital diet

was served throughout the experiment. The riboflavin and nitrogen contents of the diets were varied by adjustment of the milk intake. During periods 1 and 2, the milk intake was restricted to 300 gm daily and for periods 3 and 4, the intake was increased to 1200 gm of milk per day. Daily supplements of 5 mg riboflavin were given during periods 2 and 4. Fourteen days of dietary adjustment preceded each 7-day balance period during which the intakes and excretions of nitrogen and riboflavin were determined. The urinary excretion of riboflavin following a test dose of 3 mg riboflavin was measured on the last day of each balance period. The average daily intakes of riboflavin for the four periods were 1.35, 6.41, 2.60 and 7.79 mg. The average daily excretions were 0.31, 3.53, 1.08 and 5.63 mg riboflavin, respectively. The retentions of nitrogen by the tuberculous women were similar to those of healthy women at comparable intakes. All of the subjects were in nitrogen equilibrium or retaining nitrogen at intakes above 10.00 gm daily. Analysis of covariance has been applied to the data and the possible interrelationships of riboflavin and nitrogen metabolism will be discussed.

Lysine requirement for growing pigs. M. J. BRINEGAR (by invitation), J. K. LOOSLI, HAROLD H. WILLIAMS, and L. A. MAYNARD, *Depts. of Animal Husbandry and Biochemistry and Nutrition, Cornell University, Ithaca, N. Y.* Various levels of L-lysine monohydrochloride were added to a diet containing linseed meal supplemented with histidine and methionine for pigs averaging 19 kg in weight. The basal diet consisting of 10.6% protein contained 0.34% lysine as determined microbiologically using *Leuconostoc mesenteroides*. The experimental diets were made up to contain 0.34%, 0.42%, 0.50%, 0.58%, and 0.74% pure L-lysine. The first 4 levels of lysine were fed to 3 pigs each and the 0.74% level was fed to 2 pigs. Protein efficiency ratios over a 4-week feeding period and biological values during a 5-day nitrogen balance were studied. The averages of the gm gain in weight per gm protein consumed were 2.6, 2.85, 3.12, 3.47, and 3.49 for each of the respective lysine levels of 0.34%, 0.42%, 0.50%, 0.58%, and 0.74%. The average biological values for the corresponding lysine levels were 52, 51, 61, 73, and 72. Each level of dietary lysine up to 0.58% increased the protein efficiency and the biological value, but the 0.74% level caused no further improvement. These data show that with a diet containing 10.6% protein, having a biological value of 73, growing pigs require approximately 0.6% of L-lysine in the ration.

Acetylation in diabetic rats. FRIXOS CHARALAMBOUS (by invitation) and D. MARK HEGSTED, *Dept. of Nutrition, Harvard School of Public Health, and Dept. of Biological Chemistry, Harvard Medical School, Boston, Mass.* The ability of alloxan-diabetic rats to acetylate p-aminobenzoic

acid (PAB) was compared to that of normal rats by injecting 1 mg of PAB intraperitoneally, collecting the following 24-hour urine, and analyzing the urine for total and free PAB. All animals received a purified diet containing casein, salts, glucose, corn oil, cod liver oil and riboflavin, thiamine, nicotinic acid, pantothenic acid, and pyridoxine. Acetylation gradually decreased after the onset of diabetes and eventually fell to 62% of the dose as compared to 76% in the non-diabetic controls. Induced diuresis in the normals did not decrease acetylation. Acetylation in the diabetic animals returned to normal after the injection of insulin, citrate, α -ketoglutarate, succinate, fumarate, malate, oxaloacetate, diacetyl, acetylphosphate, and ATP. Increasing the level of fat in the diet from 5 to 30% had a similar effect, as did starvation for 24 hours. Injections of pyruvate, lactate, glyceryl diacetate, acetoin, butylene glycol, methyl ester of acetoacetic acid, phosphate salts, adenylic acid, and pantothenic acid failed to restore acetylation to normal in the diabetic rats. None of the compounds tested affected the acetylation in normal animals. These findings are in agreement with the *in vitro* work of Lipmann *et al.* (*J. Biol. Chem.*, 160, 173, 1945) that acetylation requires high energy phosphate compounds. It appears that in the diabetic animal the regeneration of such high energy compounds is below normal.

Excretion of ascorbic acid on supplements of cantaloupe and crystalline ascorbic acid. SHIH DZUNG CHEN (by invitation) and CECILIA SCHUCK, *Nutrition Lab., School of Home Economics, Purdue Univ., Lafayette, Ind.* Four senior college women majoring in nutrition served as subjects. The study was divided into 3 periods: a saturation period of 5 days during which time the subjects, while consuming their regular diets, were given 200 mg of ascorbic acid daily in tablet form; a test period of 6 days on a constant basal diet supplemented daily with 40 mg of pure crystalline ascorbic acid; a second test period with approximately the same ascorbic acid intake, but with cantaloupe as the supplement to the basal diet. The 2,4-dinitrophenylhydrazine method for reduced and dehydroascorbic acid (*J. Biol. Chem.* 174:201, 1948) was used for the analysis of the diet and the cantaloupe supplement and for determining the urinary excretion. Since the excretions for the first 2 days of the 6-day test periods reflected the large intake of ascorbic acid during the saturation period these were not considered in the evaluation of the data. With an intake of 74 mg of ascorbic acid (reduced and dehydro) the average daily amounts excreted during the crystalline ascorbic acid period by the 4 subjects were 49.24, 47.65, 47.43, and 38.30 mg respectively. Corresponding amounts excreted during the cantaloupe period with a daily intake of 72 mg ascorbic acid

were 57.54, 58.63, 41.88, and 34.81 mg. The figures show an increased excretion during the cantaloupe period for 2 of the subjects and a slightly decreased excretion for the other two.

Determination of SLR factor in the liver and urine of rats fed on various diets. BACON F CHOW, LOIS HALL (by invitation), SHIRLEY DE BIASE (by invitation) and LOIS BARROWS (by invitation) *Division of Pharmacology, The Squibb Inst for Medical Research, New Brunswick, N. J.* Protein depletion causes a marked decrease in protein and enzyme contents of the liver. This report deals with the effect of inanition on the concentration of the SLR factor (Elvehjem, J. Biol. Chem. 167: 86, 1947) in the liver of rats. It was found that if the liver were homogenized with an ice cold saline solution immediately after its removal from the animal, the activity of such a suspension increased some 10-fold upon incubation at 37°C. A maximum was, however, reached after 8-24 hours at this temperature. The results of assay of this factor in the homogenized livers of normal and seven-days-fasted rats, after appropriate length of incubation, demonstrated that inanition brought about a marked loss in the total amount of the potential activity, when expressed in units of activity per hundred grams body weight of the animals before fasting. The excretion of the SLR factor in urine was also studied. The renal excretion of this factor decreases on feeding a diet low in protein but adequate in calories and vitamins, but increases, if liver is given as a supplement either orally or intraperitoneally.

Weight of liver and liver glycogen of rats after dietary restriction and rehabilitation. RUTH M. CLAYTON and ESTHER DA COSTA (introduced by ROBERT E. JOHNSON) *U. S. Army Medical Nutrition Lab., Chicago, Ill.* Liver weights of 72 male rats fed during 13 weeks either a low calorie, modified or synthetic vegetable diet and of 120 rats changed from these diets to either high protein, high fat or high carbohydrate were determined. The glycogen of the liver of half of these rats was determined. The average weight of 42 control livers was 12.16 gm. with a total glycogen of 0.24 gm. The average weights of livers following the low calorie, modified carrot or synthetic vegetable diet were 7.13, 7.5 and 5.47 gm., respectively. The average total liver glycogens following the low calorie, modified carrot or synthetic vegetable diet were 0.12, 0.24 and 0.06 gm., respectively. After 72 hours of rehabilitation with a high protein, high fat or high carbohydrate diet following the low calorie diet were 13.2, 10.19 and 10.98 gm., respectively. Average liver weights from rats refed following the modified carrot or synthetic vegetable diet followed a similar pattern of increased weight. After 72 hours of rehabilitation liver glycogen increased in all diets but decreased after 96 hours.

After 13 weeks of rehabilitation on a high protein diet, liver glycogens were at the control level, on a high fat diet below and on a high carbohydrate diet above the control level.

Function of the ceca in the domestic fowl. J. R. COUCH (by invitation), D. R. KNIGHT (by invitation), HARRY GERMAN (by invitation) and P. B. PEARSON *Agricultural and Mechanical College of Texas, College Station, Texas.* Broad-breasted Bronze mature turkey toms and White Leghorn pullets were each selected at random from flocks on range and killed. The gastrointestinal tracts were removed and separated into two parts for sampling. The first section was made up of the ceca while the second consisted of the tract below the duodenum less the ceca. The contents were removed from each of these sections and analyzed for riboflavin, niacin, pantothenic acid, folic acid and biotin. The cecal contents contained approximately 1.5 times as much niacin, twice as much riboflavin, 2.5 times as much pantothenic acid, 6 to 8 times as much folic acid, and 10 times as much biotin as the intestinal contents. Identification studies of the microflora of the two sections of the GI tract showed that essentially the same flora existed in the ceca as in the rest of the tract. The ceca was removed from pullets which were placed in individual cages with raised screen bottoms. After 2 months a 24-hour collection of feces was made from the cecectomized birds and from normal pullets. There was no difference in the riboflavin, niacin, pantothenic acid, folic acid and biotin content of feces of cecectomized and normal birds fed a practical all-mash diet. These birds were then placed on a low biotin diet with starch as the carbohydrate. Biotin content and hatchability of the eggs will be reported as measures of intestinal synthesis in birds with and without the ceca.

Desoxypyridoxine and development of the chick embryo. W. W. CRAVENS and E. E. SNELL *Depts. of Poultry Husbandry and Biochemistry, Univ. of Wisconsin, Madison, Wis.* Injecting 1000 μ g of desoxypyridoxine into the hen's egg at 0 hours of incubation results in nearly 100% mortality of the embryos by the end of the fourth day of incubation and all embryos died prior to hatching. 250 and 500 μ g injected at 0 hours caused a reduction in hatchability, but some live chicks were obtained. These inhibitory effects were prevented by simultaneous injection of sufficient amounts of pyridoxal HCl, pyridoxamine 2HCl or pyridoxine HCl. The ratio of vitamin to inhibitor which permitted approximately 50% of the embryos to produce live chicks were pyridoxal HCl 1/20, pyridoxamine 2HCl 1/50, and pyridoxine HCl 1/100. In contrast to the results at 0 days, injection of 100 μ g of desoxypyridoxine at 6 days of incubation was innocuous. At this time the toxic level was found to be 2.5-5.0 mg/egg. However,

this toxicity was not due to a competitive anti-vitamin action of the inhibitor since it could not be prevented by any of the three forms of vitamin B₆. At similarly high levels (more than 2.5 mg/egg) pyridoxal HCl proved toxic. Pyridoxine HCl was somewhat less toxic while pyridoxamine 2HCl was non-toxic at the highest level tested (10 mg/egg).

Effect of dietary restriction and rehabilitation on serum protein of male rats ESTHER DA COSTA and RUTH CLAYTON (introduced by ROBERT E. JOHNSON) *U S Army Medical Nutrition Lab, Chicago, 9, Ill*. The mean total serum protein of 42 control rats was 6.4 gm % and the A/G ratio was 1.34. Seventy-two rats kept 3 weeks on a low calorie, modified carrot or synthetic vegetable diet had total serum protein values of 6.14, 5.41 and 6.21 gm % and A/G ratios of 1.43, 1.16 and 1.05 respectively. After 13 weeks of rehabilitation following the 3 types of restriction 120 rats were rehabilitated with a high protein, high fat or high carbohydrate diet. After 48 and 96 hours of refeeding, the high protein and high fat rats had slightly higher serum proteins than the controls but the high carbohydrate rats had significantly lower serum proteins. After 13 weeks of rehabilitation all types of re-fed rats showed normal protein values. During the first 48 hours of rehabilitation the A/G ratio of the rats on the high protein and high fat diets fell below 1.0, i.e. due to a lowering of the albumen. By 96 hours of refeeding all A/G ratios had reached 1.0 and by 6 weeks of refeeding they returned to normal. The rats kept on a low calorie, modified carrot or synthetic vegetable diet after 13 weeks lost an average of 39.6, 42.2 and 44.5% in weight but only the rats on the modified carrot diet had serum protein concentrations below normal.

Tryptophan-nicotinic acid relationship in the developing chick embryo CHARLES A. DENTON (by invitation) W. L. KELLOGG (by invitation), W. E. ROWLAND (by invitation) and H. R. BIRD *Bureau of Animal Industry, Agr Res Adm U S D A, Beltsville, Md*. The developing chick embryo synthesizes nicotinic acid and at the same time decreases in tryptophan content. The eggs contained on the average 36 micrograms of nicotinic acid, whereas the average content of the chicks was 1080 micrograms. The tryptophan decreased from 116 mgs (average content of the eggs) to 72 mg (average content of the chicks). Injection of 25 mg of tryptophan into the eggs on the 10th day of incubation resulted in a significant increase in the nicotinic acid content of the chicks. Injection of 10 mg of nicotinic acid into the eggs caused a slight increase in the nicotinic acid content of the chicks, but did not change the tryptophan content.

Effects of pteroylglutamic acid, injectable liver extract, and ascorbic acid on dietary glycine toxicity JAMES S. DINTING (by invitation), CECILIA K. KEITH (by invitation), JOHN R. TOTTER

and PAUL L. DAY *Dept of Biochemistry, School of Medicine, Univ of Arkansas, Little Rock, Ark*. A study was made of the effect of pteroylglutamic acid (PGA), injectable liver extract (LE), and ascorbic acid on growth and fecal porphyrin excretion of rats receiving purified diet containing 10% glycine. The purified diet without glycine was fed to a control group. The average weekly gains over a 5-week period for the groups were: control 25.3 gm, high glycine 5.6 gm, high glycine + PGA 19.8 gm, high glycine + LE 12.9 gm, high glycine + PGA + LE 21.1 gm, and high glycine + ascorbic acid 9.3 gm. Both PGA and LE significantly improved growth when added to the high glycine diet ($p < 0.01$). PGA was more effective than LE in improving growth under these conditions and a combination of PGA and LE did not improve growth above the level obtained by PGA alone. Although addition of ascorbic acid to the high glycine diet improved growth slightly, the increase was not statistically significant. The fecal porphyrin excretion of rats receiving the high glycine diet was considerably lower than that of the control rats. Additions of PGA, LE, or ascorbic acid to the high glycine diet increased the fecal porphyrin excretion. The greatest increase in porphyrin excretion was obtained by the addition of a combination of PGA and LE to the high glycine diet; fecal porphyrin excretion under these conditions was elevated above that of the control rats.

Vitamin B₁₂—a growth factor for young rats GLADYS A. EMERSON, ELIZABETH WURTZ (by invitation) and MARY E. ZANETTI (by invitation) *Merck Inst for Therapeutic Research, Rahway, N J*. The rat requires a factor which is present in liver and other animal proteins for normal growth and successful propagation. The influence of vitamin B₁₂ on the progeny of rats maintained during gestation and lactation on a diet containing 60% soybean meal has been investigated. One group of animals received 5 γ of vitamin B₁₂ daily from impregnation while a like number of untreated females served as controls. The size and birth weights of the litters cast by the rats in each group were the same. However, the weaning weights (28 days) of the young from mothers receiving vitamin B₁₂ averaged 50% more than did those from the untreated females. The offspring from each group were segregated at weaning into 2 subdivisions, in one the animals were given 0.5 γ of vitamin B₁₂ daily for 90 days and the others were unsupplemented. The weight increments of the males from the several groups were as follows: control mothers, young undosed, 151 gm; control mothers, young dosed, 257 gm; treated mothers, young undosed, 229 gm; treated mothers, young dosed, 283 gm. The feeding of vitamin B₁₂ to the young of control mothers resulted in body weights that were 100 gm in excess of those of the unsupplemented animals.

Since the undosed young of the treated mothers grew for 2 months at a rate approximating that of the dosed young from the control mothers, it would appear that vitamin B₁₂ is stored during the suckling period. The red and white cell counts of the individuals of all groups fell within the normal range.

Relation of choline intake to survival in rats fed p-dimethylaminoazobenzene R W ENGEL *Lab of Animal Nutrition, Alabama Polytechnic Inst, Auburn, Ala*. When immature male and female rats of approximately 200 gm body weight were subsisted for 2 months on a low-protein diet deficient in choline, they gained an average of 1.2 gm/rat/week. Inclusion in the diet of p-dimethylaminoazobenzene at the 0.6% level for a subsequent 7-week feeding period resulted in the death of 7 of 8 rats with an average survival period of 28 days. When the diet was fortified with choline (2 gm/kg), the average body weight gain during the initial 2-month feeding period was 3.0 gm/rat/week and 8 of 8 rats survived the subsequent 7-week feeding period when p-dimethylaminoazobenzene was included in the diet at the 0.6% level. All the animals receiving the choline deficient diet exhibited gross evidence of liver cirrhosis and a marked accumulation of a clear serous fluid in the body cavities at autopsy. Only mild kidney damage was evident. The livers of the control animals receiving choline were normal in appearance, and no gross pathologic changes were evident in any tissues at autopsy after 7 weeks of p-dimethylaminoazobenzene feeding. The basal diet employed consisted of alcohol-extracted casein 2, alcohol-extracted peanut meal 10, sucrose 63.5, salts 4.4, L-cystine 0.1, lard 19, and cod liver oil 1, and was fortified with known accessory factors.

Chronic vitamin A deficiency in 3 inbred strains of mice PAUL F FENTON (by invitation), RUTH E SHRADER (by invitation) and GEORGE R COWGILL *Yale Nutrition Lab, Dept of Physiological Chemistry, and Dept of Anatomy, Yale Univ, New Haven, Conn*. Weanling mice of the C₅₇, A and I strains were fed an artificial diet containing no added vitamin A. Growth rates of the C₅₇ mice were less than those of the A strain although substantial growth occurred in both strains. Growth was more seriously retarded when the corn oil of the diet was replaced by hydrogenated cottonseed oil and vitamin E was omitted. A striking early feature of vitamin A deficiency in C₅₇ mice was the graying or bronzing of the normally black fur. Distribution of the fur changes differed markedly from that seen in pantothenate deficiency. The vitamin A content of the livers was reduced to a very low level. Most mice survived many months without outward symptoms of deficiency. A substantial group was sacrificed when about 9 months old and organ weights determined. The most consistent findings

regarding the blood picture were reductions in the red cell counts, hemoglobin levels and hematocrit values. Infection was frequently present. Many animals retained extensive fat depots despite 8 months on the deficient diet. Histological and histochemical studies were carried out on liver, kidney, spleen, thymus, testes and adrenals, and, when necessary, on other tissues. Several vitamin A-deficient male mice were injected with three doses of estradiol benzoate. Two months later the accessory reproductive structures were found to be greatly distended. They presented a histologic picture similar to that seen in mice treated for a long time with large doses of the estrogen.

Unidentified vitamins of the B complex required by certain insects G FRAENKEL (introduced by H E CARTER) *Dept of Entomology, Univ of Illinois, Urbana, Ill*. Many insects which normally live on grain or flour can be easily grown on 'synthetic' diets and are excellent material for nutritional studies. It is now an established fact that insects in general require all the known vitamins of the B-complex, including biotin and pteroylglutamic acid, with the exception of paraaminobenzoic acid and possibly inositol. Some insects seem to develop optimally on 'synthetic' diets in the absence of any sources of unidentified factors. With the mealworm, *Tenebrio molitor*, there is clear-cut evidence for the need of one additional factor present in yeast or liver, tentatively called B_T, which is not adsorbed on charcoal and has proved very elusive in all attempts to be precipitated from the aqueous phase. In this respect, and certain chemical characteristics as well, it bears a close resemblance to streptogenin, though the absence of B_T activity in casein excludes identity of the two factors. The need for at least 2 other unidentified members of the B-complex has been demonstrated for the flour beetle, *Tribolium confusum*. Growth on a 'synthetic' diet is slow by comparison with an optimal natural diet—wholemeal flour. A certain improvement is achieved by adding 2½% of the water-insoluble fraction of yeast, but a still greater improvement results from adding 1% dry yeast. For reasons still unexplained these deficiencies are more marked if starch is used as the carbohydrate, as compared with glucose. B_T concentrates failed to have any effect on *Tribolium* in diets deficient in one or two of the missing factors.

Effect of gossypol on the body weight of rats ALFRED H FREE and HELEN M FREE (by invitation) *Miles Research Labs, Elkhart, Ind*. Gossypol is an organic compound present in the pigment gland of the cottonseed. It has long been recognized that the inclusion of large amounts of unheated cottonseed meal in the diets of animals has a detrimental and toxic effect which has been ascribed to gossypol. Zucker and Zucker (Abstracts of Papers, 111th meeting, American Chemical So-

ciety, page 47B, 1947) have suggested that gossypol has a specific effect in reducing food intake. Further experiments have been carried out in this laboratory to determine the effect of gossypol on the body weight of rats. Gossypol was prepared from whole cottonseeds by the method of Boatner et al. (Jour Am Chem Soc 69 1268, 1947). Growth studies with young rats were made in which the animals were maintained on a standard diet and were given daily supplements of gossypol suspensions by stomach tube. In 7 experiments of this type employing 3 different preparations of gossypol, uniform results were obtained in which animals on higher intakes of gossypol died, whereas those on intakes that were $\frac{1}{2}$ or $\frac{1}{3}$ of the toxic amount grew at rates comparable to the control group which did not receive gossypol. Adult rats showed no significant weight change when given a daily supplement of gossypol that was one-half the toxic amount. Starvation experiments with rats indicated that the weight loss of animals receiving minimal lethal quantities of gossypol was much less than the weight loss of animals dying of starvation.

Rat-repletion studies with amino acid solutions

Rôle of non-essential amino acids. DOUGLAS V. FROST and HARRY R. SANDY (by invitation) *Nutritional Research Division, Abbott Labs., North Chicago, Ill.* Weight response of adult protein-depleted rats to dry proteins, liquid protein hydrolysates or solutions of amino acids fed separately from protein-free diet was studied at controlled critical levels of nitrogen. A 5% solution was fed to supply twice Cannon's essential amino acid minima of tryptophan 13, phenylalanine 37, leucine 77, isoleucine 66, methionine 35, threonine 45, lysine 51, histidine 22 and valine 53 mg/rat/day. Discounting the D-isomers of isoleucine, threonine and valine, this provided about 100 mg N/day. Only half of the liquid allotment representing this mixture was consumed and the weight response was low. Intake and response were nearly doubled by isonitrogenous replacement of 10 parts of essentials by arginine or glycine. Nitrogen efficiency ratios were high in each instance and compare favorably with the highest values calculated for standard proteins. Glutamic acid, in presence of arginine, glycine and alanine, led to a further improvement in acceptability and weight response. Complete hydrolysates of fibrin fortified with tryptophan were taken with greater avidity than amino acid mixtures, even though nitrogen efficiency was somewhat lower for the former. These effects were checked by repeated experiments in paired groups. The data suggest that absence of nitrogen other than essential amino acid N imposes a physiologic burden which is reflected in decreased appetite, but not in decreased nitrogen efficiency. Possible inhibitory effects of the D-amino acids may account

in part for the lesser avidity for amino acid mixtures than for complete protein hydrolysates.

Decrease in the storage of thiamine in tissues from supplementing the diet with live bakers' yeast. FUNG-HAAN FUNG (by invitation), RUTH J. AANESS (by invitation) and HELEN T. PARSONS *Dept. of Home Economics, Univ. of Wisconsin, Madison, Wis.* It has been established that when live bakers' yeast is ingested by human subjects, not only the yeast thiamine but also food thiamine consumed simultaneously fails to be returned in the urine in normal amounts, presumably because it is taken up in the digestive tract by yeast cells. However, about 80% of the nitrogen of the yeast cells was returned in the urine of the subjects. The hypothesis of an anti-enzyme analogous to folic acid anti-conjugase was untenable inasmuch as free thiamine was itself influenced by live yeast. Hence it became important to establish by direct proof whether or not absorption and storage of thiamine were actually interfered with by live yeast. Weanling pigs were found to be satisfactory test animals. Those fed live bakers' yeast in addition to the basal ration stored only about $\frac{1}{2}$ as high a percentage of the total thiamine intake as pigs without this supplement. In all animals tested, about $\frac{1}{10}$ of the total storage occurred in the skeletal muscles. Supplementing with live yeast depressed the urinary thiamine and increased the fecal values quite comparably with previous results in this department on college women. This fact, considered with the decrease in thiamine storage in the tissues of pigs fed the yeast dose, substantiates the earlier conclusion that the ingestion of live bakers' yeast interferes with the absorption of thiamine by human subjects.

Biotin deficiency in ducklings and the histopathology of the heart. JAMES W. GODDARD and ROBERT E. OLSON (introduced by FREDERICK J. STARE) *Dept. of Nutrition, Harvard School of Public Health, Boston, Mass.* Studies in biotin-deficient ducks (J Biol Chem 175 503, 1948) have shown that the respiration, pyruvate and succinate utilization of cardiac muscle slices *in vitro* is markedly depressed below normal. In view of this the histopathology of the heart in biotin deficiency was investigated. Biotin deficiency was induced in one-day old ducklings by feeding a purified diet low in biotin and supplemented with 20% egg white. Deficient ducks were killed by decapitation at intervals after their growth had ceased and perosis developed, the hearts removed, weighed, fixed *in toto* in Romeis' fixing fluid and paraffin sections stained with Masson's trichrome, Mallory's phosphotungstic acid hematoxylin, and Heidenhain's iron hematoxylin. Grossly, the hearts from the deficient ducks were larger, heavier (50%) and paler than those from pair-fed controls. Microscopically, the hearts from the deficient ducks showed disruption

and lysis of myocardial fibrils, disintegration of anisotropic hands, and granularity and vacuolation of the muscle fibers. The Purkinje cells showed marked disorientation and disappearance of their myofibrils. In severe cases, these myofibrils and even whole Purkinje cells were replaced by connective tissue. The endocardial cells showed occasional hyperplasia, chiefly in areas over involved Purkinje cells, and desquamation. The pericardium and vessels were essentially negative.

Resurvey of nutritional status in Norris Point, Newfoundland. GRACE A. GOLDSMITH, WILLIAM J. DARBY, RUTH STEINKAMP (by invitation), ANNE STOCKELL (by invitation) and ELLEN McDEVITT (by invitation). *Dept of Medicine, Tulane Univ School of Medicine, New Orleans, La, Depts of Biochemistry and Medicine, Vanderbilt Univ School of Medicine, Nashville, Tenn.* Evaluation of the nutriture of 126 persons from 4 population segments—pre-school, pre-adolescent, mothers of children under 2 years, and other adults—was made in Norris Point, Newfoundland, in July, 1948. Following a comparable study in 1944 (*J Lab Clin Med* 30:475) compulsory enrichment of flour was instituted. Dietary patterns were similar in the 2 studies, $\frac{1}{4}$ or more of the calories of half the subjects being derived from flour and cereals. Low intakes of ascorbic acid, calcium, vitamin A and riboflavin occurred in 25 to 50% of the examinees. The incidence of subjective complaints attributable to malnutrition was essentially the same in both surveys. Physical findings in 1948, as compared to 1944, showed somewhat less nasolabial seborrhea, thickening and pigmentation of pressure points, circumcorneal injection, neurologic changes, and a definite decrease in the incidence and severity of lingual lesions. The same or increased incidence was noted for cheilosis, conjunctival injection, dental caries, gingival changes, follicular keratosis and angular fissuring. Less conjunctival thickening was observed in pre-school children, an equal amount in other groups. Serum protein, hemoglobin, and vitamin A levels were generally satisfactory. Distribution of serum ascorbic acid was 0.13, 0.39, and 0.65 mg/100 cc for the first, second, and third quartiles, respectively. Four-hour urinary excretion, after an oral test dose of vitamins, was frequently low for riboflavin, but usually comparable to that in a group of normal laboratory subjects for thiamine and N'-methylnicotinamide. Correlations between dietary intake, physical signs, and laboratory findings will be presented and the significance of the data discussed.

Interrelation of age, serum cholesterol, and basal metabolism of women. MARY R. GRAM (by invitation) and RUTH M. LEVERTON. *Human Nutrition Research Lab, Univ of Nebraska, Lincoln, Neb.* Serum cholesterol and basal metabolic rate were determined on 130 women between

the ages of 18 and 70 years and living on self-chosen diets. Total serum cholesterol was determined fasting blood samples by the Liebermann-Burch reaction modified by Hoffman. Basal metabolic rate was determined with a Benedict-Roth respiration calorimeter and the results compared with normal values calculated on the basis of ideal weight by the method of DuBois as modified by Boothby and Sandiford. The women studied were in the following age groups: 18-25 yr, 52 subjects; 30-40 yr, 28 subjects; 40-50 yr, 28 subjects; 50-60 yr, 32 subjects; and 60-70 yr, 20 subjects. The mean serum cholesterol for each age group was 177.4, 200.7, 250.6, and 257.4 mg % respectively. Analysis of variance indicates this increase of cholesterol with increasing age is significant. The mean basal metabolic rate for all women was 7% below the standard. The means of the basal metabolic rates for each age group were not significantly different. The relationship of basal metabolic rate to serum cholesterol and other blood values is being investigated for each age group.

Goiter in West Virginia. ISIDOR GREENWALL. *Dept of Chemistry, New York Univ College of Medicine, New York City.* In 1928, Kimball, relying upon statements by 'older physicians' in Charlestown, claimed that goiter had been 'exceptionally rare' in the Kanawha valley before 1900 and that the high incidence in 1922 was due to replacement of local salt by a refined product, "the only change in food or water" that had occurred in the interval. The Journal of the American Medical Association has recently reiterated that claim (135:434, 1947). The only information available regarding the iodine content of the local salt is given by Grimsley (West Virginia Geological Survey, Reports, vol. 4) the brine of the one well open in 1909 contained only one part of NaI per 61,400 parts of NaCl. Moreover, Drake, writing from 'among the upper waters of the Kanawha' in 1850, stated "Goitre. Cases are scattered here and there. I think they are not more numerous in proportion to the population than in the valleys of the Scioto and Cuyahoga" (Western Lancet 11:558). Earlier reports of goiter in West Virginia are mentioned by Barton (Memoir Concerning Goiter, 1800). In 1893, goiter had disappeared from many parts of the country in which it had been endemic (Osler, *Am J Med Sci* 106:503). Later, the disease reappeared. This sequence was well illustrated at Edmonton. There, too, an 'older physician' denied that the disease was present before 1900. However, cretins and large goiters were common in 1820 and many young girls had goiters as late as 1863 (Greenwald, *Bull His Med* 17:229, 1945).

Effect of various amino acids on rats receiving niacin-tryptophan deficient rations. L. V. HANKES, L. M. HENDERSON (by invitation) and C. A. ELVEHJEM. *Dept of Biochemistry, College of Agri-*

culture, *Univ of Wisconsin, Madison, Wis* Previous work has shown that 0.078% DL-threonine or 0.204% DL-phenylalanine will cause a growth inhibition in rats on a 9% casein sucrose ration deficient in niacin. The active isomers were found to be L-threonine and D-phenylalanine. When the 0.2% L-cystine, which is normally included in the ration, was omitted, almost normal growth was obtained in the presence of 0.078% DL-threonine, 0.208% DL-phenylalanine, 2% acid hydrolyzed casein, or 2% glycine. However, the addition of 0.2% L-cystine with any of the above materials caused growth inhibition. When 0.2% DL-methionine replaced 0.2% L-cystine a growth inhibition occurred only with 0.078% DL-threonine or 2% acid hydrolyzed casein. Urine excretion studies indicated that acid hydrolyzed casein did not affect the amounts of N-methylnicotinamide or nicotinic acid excreted. DL-threonine (0.078%) in the presence of either L-cystine or DL-methionine did not affect the nicotinic acid levels in the urine. Since rats on a 9% casein dextrin ration showed a growth inhibition only with 6% gelatin, and not with 0.078% DL-threonine or 2% acid hydrolyzed casein, the effect of coprophagy on growth inhibition was studied. Six % gelatin caused a growth inhibition when the rats were in a square cage, but not when in a tube cage. Feces were analyzed for niacin.

Use of enriched cereals in certain diets consumed in the south. HARRIET A. HARLIN and BEULAH D. WESTERMAN (introduced by MARTHA M. KRAMER) *Dept of Foods and Nutrition, Kansas Agr Exp Sta, Kansas State College, Manhattan, Kan* Growth studies were made on young albino rats fed diets based upon the food consumed by certain low income groups in the South, to determine the significance of the use of enriched flour as a source of the B vitamins. The Negro tenants of the Mississippi Delta consume diets made up primarily of molasses, fat, cereals and black-eyed-peas with small quantities of eggs, vegetables, fruits and milk. When 58% of the calories in such a diet was derived from cereals, the growth of the rats consuming the diets containing enriched flour as the cereal component was greater than those consuming an equal quantity of non-enriched flour. When 45% of the total calories were derived from cereal, there was no difference in the growth gains made by the rats on the diets containing enriched and non-enriched flour. Certain people in South Carolina consume diets consisting of limited quantities of fat, meat, milk, eggs, vegetables, fruits and large quantities of cereals. When such diets were fed to rats and 50% of the total calories of the diet was furnished by enriched flour the animals with enriched flour in the diet made on the average 10 gm greater growth gains than did those with non-enriched flour in the diet. When the enriched and non-enriched flour were fed at a level of 40 and 33%

of the total calories in the diet no difference was noted in the average weight gains of the rats.

Concurrent feeding of amino acids. RICHARD HENDERSON (by invitation) and ROBERT S. HARRIS *Nutritional Biochemistry Labs, Massachusetts Inst of Technology, Cambridge, Mass* Groups of weanling rats were fed a basal diet containing casein (30), corn starch (55.4), hydrogenated fat (10), tryptophan (0.17), histidine (0.13), salt mixture (4) and vitamin mixture (0.36). Control groups received the basal diet + 1% lysine. Test groups received the basal diet and the basal diet + 2% lysine at alternate feedings. The lysine replaced equal weights of corn starch in the diet. Groups were fed (1) one hour and fasted 7 hours, (2) one hour and fasted 5 hours and (3) one hour and fasted 3 hours throughout successive experiments lasting 27 days. A time-interval feeder was devised for the automatic opening and closing of the feeding jars. Significant differences were noted in nitrogen retention and in body weight gain, weight gain/gram of diet eaten, weight gain/gram of lysine eaten. These differences were greater as the feeding intervals lengthened. Thus a delay of 3 hours or longer, in the feeding of lysine as a supplement to a lysine-low diet interfered with metabolism. Lysine must be fed concurrently with other amino acids in the diet for most efficient utilization by the rat.

Vitamin B₁₂ in swine nutrition. A. G. HOGAN and G. C. ANDERSON (by invitation) *Depts of Animal Husbandry and Agricultural Chemistry, Univ of Missouri, Columbia, Mo* Six pigs were taken from their mothers at 2 days of age and transferred to cages with wide-mesh wire floors. They were reared on synthetic milk which included 'vitamin-free' casein, sucrose, corn starch, lard, mineral salts, and generous supplies of vitamins A, D, E, K, thiamine, riboflavin, pyridoxine, pantothenic acid, niacin, choline, biotin, folic acid and inositol. Three of the pigs were given intramuscular injections of crystalline vitamin B₁₂ (Merck) at 3-day intervals, until they were 38 days old. One pig received a total of 50, a second received 100, and the third received 200 mcg. All 6 pigs grew at about the same rate for the first 6 weeks. In the following 4-week period the pigs that received the injections made an average gain of 26.8 lb, the others gained 15.9 lb. In the following 6-week period one pig that did not receive vitamin B₁₂ died, unexpectedly, and one has not gained consistently. The third began to decline and when injected with a total of 15 mcg of vitamin B₁₂ it began to gain at a moderate rate. The 3 that had received the vitamin injected grew at a uniform rate with an average gain of 58.8 lb, which is exceptional for that age. Three sows in all have been reared on synthetic diets. Two farrowed but were unable to rear their litters. The third never became

pregnant, presumably because of a constriction in each Fallopian tube

Role of methionine in the protein metabolism of the rat CECILE HOOVER (by invitation), PEARL SWANSON, and HELEN MERRIAM STEWART (by invitation) *Nutrition Laby, Foods and Nutrition Section, Iowa Agr Exp Sta, Iowa State College, Ames, Iowa* Methionine, when added as a supplement to a nitrogen-poor diet offered to rats for a period of 21 days, exerts a marked body-sparing action. It has been postulated that in its absence, the body raids its own tissues to secure this compound for the fabrication of an essential metabolite(s). This hypothesis is being tested by studies of the partition of urine excreted by rats under various experimental conditions. The reduced excretion of urinary nitrogen resulting from the dietary addition of methionine is due to a marked decrease in both the total and relative amounts of urea nitrogen. Effects induced by the supplementary feeding of certain analogs of methionine also have been investigated. An accelerated catabolism, for example, accompanies the administration of ethionine. Although the quantity of nitrogen excreted is increased by 148 mg, the excretion of urea remains constant. Ethionine apparently acts like an antagonistic substance, thereby indicating that methionine occupies a key position in some metabolic reaction, and is important in this connection as a whole molecule rather than by virtue of specific constituent groupings. With caloric restriction, the elimination of fat from the test ration of rats results in a striking increment in urinary nitrogen due to increased quantities of urea. The addition of methionine averts the catabolic action of the low fat diet under these conditions. The ameliorative influence of dietary fat appears to rest on its ability to reduce the catabolism of compounds, the end products of which show up in the non-urea nitrogen fraction of urine.

Fatal lung hemorrhage and liver damage in rats prevented by vitamin E E L HOVE, D H COPELAND (by invitation) and W D SALMON *Laby of Animal Nutrition, Alabama Polytechnic Inst, Auburn, Ala* Young rats died suddenly after an average of 53 days on a Vitamin E-free, low-casein, high-fat diet. A sex difference in incidence was apparent: death came to 80% of the males (30/37) but only 30% of the females (3/10). No spontaneous deaths occurred among 28 litter mate controls receiving 7 mg DL alpha tocopherol weekly. The diet contained water-washed casein 10, lard 19, cod liver oil 1, salt mixture 4, sucrose 66, choline 0.2, and an abundance of B vitamins. Necropsy revealed 3 major types of lesions: massive hemorrhage in the lungs, distension of small and large blood vessels of the body, and grossly evident liver damage which histologic section showed to be zonal necrosis. Evidence of Vitamin-E deficiency was shown by

blanching of the teeth, testicular atrophy, creatin-urea, and depressed growth (0.86 gm/day as compared with 1.26 gm/day for controls). Methionine, cystine or theophylline (0.1%) did not protect, although a higher casein level did. With 18% casein in the E-low diet, growth was optimum, and the rats remained in apparent good health for a year. The protective factor in casein could be destroyed by hydrogen peroxide. Death and liver damage occurred in 5 of 6 rats on E-low diets containing 18% oxidized casein fortified with tryptophane and methionine. The DL-methionine requirement for maximum growth was over 1% although this level did not protect against the acute Vitamin-E deficiency.

Influence of vitamin E on the creatine and creatinine excretion of rats poisoned with CCl₄ E L HOVE *Laby of Animal Nutrition, Alabama Polytechnic Inst, Auburn, Ala* A sharp increase in creatine excretion and a reduction in creatinine excretion has been observed in rats poisoned with CCl₄. The same condition occurs as the result of a chronic vitamin-E deficiency. Therefore a study was made of the influence of vitamin E on the creatine-creatinine excretion pattern following CCl₄. Groups of rats on a 10% casein, E-low diet were fed 0, 0.5, 2.5 and 12.5 mg of DL, alpha tocopherol daily for 10 days prior to injections of single doses of 1 cc of CCl₄/kg body weight. The maximum creatine excretion level, expressed as mg/rat/day, was 25 for the E-free group, but only 7 for the group fed the highest tocopherol level. The fall in the creatinine excretion was delayed in the tocopherol fed group and the return to normal values was more rapid. The lower tocopherol levels gave intermediate values. Half of the E-free control group died as the result of CCl₄. None of the tocopherol-fed rats died. The values given for the creatine-creatinine excretion of the E-free group are based on survivors.

Role of the gastrointestinal tract in the conversion of tryptophan to nicotinic acid JAMES M HUNDLEY (introduced by F S DAFT) *Experimental Biology and Medicine Inst, National Inst of Health, Bethesda, Md* Several investigators have advanced evidence indicating that the intestinal bacteria can supply a part or perhaps all of the requirement for nicotinic acid in certain species. Since tryptophan is known to be a dietary precursor of nicotinic acid, the idea has been advanced that intestinal bacteria may convert tryptophan to nicotinic acid. To test this possibility, we have studied the efficiency of conversion of tryptophan to nicotinic acid in rats before and after surgical removal of the gastrointestinal tract. The amount of urinary N'-methylnicotinamide (NMN), expressed as γ per 100 gm of rat in 24 hours, was used as an index of the amount of nicotinic acid synthesized. 100 mg of L(-)-tryptophan given subcutane-

ously in 10 cc of saline was the test dose in all instances. 26 male rats weighing about 250 gm each were maintained on a basal purified 'nicotinic acid free' diet. The rats excreted 120 γ of NMN on this diet alone. Tryptophan increased the excretion to 1274 γ . After surgical removal of the entire intestine, excepting the stomach, the basal excretion of NMN was 246 γ . Tryptophan increased the excretion to 2156 γ . After gastrectomy only, the basal excretion was 182 γ which tryptophan increased to 1864 γ . These data have been interpreted to mean that neither the stomach nor the bacteria of the intestinal tract are involved in the synthesis of nicotinic acid from tryptophan.

Comparison of sugars in the purified diet of baby pigs S. R. JOHNSON, *Dept. of Animal Industry, Univ. of Arkansas, Fayetteville, Ark.* Five litters of baby pigs were fed 'synthetic' milk in which all nutrients were in purified form. When the carbohydrate was sucrose, acute diarrhoea quickly developed, resulting in rapid weight loss and death within 48 hours unless a ration change supervened. Hemorrhagic kidney syndrome, probably like that observed in young rats on low choline sucrose-base diets, resulted from the use of sucrose. When the ration was quickly changed to cows' milk, recovery occurred. If the pigs were started on cows' milk and changed very gradually to the sucrose-base diet, they tolerated the sucrose. Addition of 16% yeast, 0.4% d-l methionine, or a double allowance of pure vitamins did not prevent the sucrose syndrome. Glucose ('Cerelease') instead of sucrose in the purified diet resulted in uneventful growth with little or no diarrhoea or kidney damage. Lactose was satisfactory in the starting ration but pigs on the lactose-base diet eventually developed chronic diarrhoea, grew more slowly than those receiving glucose, and one pig continued on the lactose diet developed probable biotin deficiency. Levulose was unsatisfactory as the carbohydrate (2 cases), and addition of sucrase enzyme to the sucrose-base diet did not improve performance (2 cases). Baby pigs could be started very successfully with only one small nursing of colostrum, cows' milk while learning to drink the first day, then with the purified diet with either glucose or lactose as the carbohydrate.

Perspiration as a factor influencing the iron requirement FRANCES A. JOHNSTON and GLADYS C. HAGEN (by invitation), *N. Y. State College of Home Economics, Cornell Univ., Ithaca, N. Y.* In studies of the iron requirement the loss of iron in perspiration is not usually taken into consideration. Unless the loss is extremely small it will raise the requirement appreciably because of the low percentage of iron absorbed from the diet. The problem of collecting perspiration free of contamination is so difficult that all we could do was obtain a value which would set a top limit to the amount of iron

that might be present. The iron content of filtered water collected from washing 2 subjects after perspiring for 2 hr at 100°F and 59-67% relative humidity was 0.02, 0.02 mg respectively. This would amount to 0.24 mg for 24 hr of profuse perspiration. Since perspiration seldom continues at a profuse rate for 24 hr, a loss as large as this would be unusual. Perspiration induced by high temperatures and humidity and collected without dilution was found to contain a mean value of 0.06, 0.05, 0.03, 0.02 and 0.04 mg/l for each of 5 subjects. Except under extreme conditions of temperature, humidity or activity, the excretion of perspiration probably does not exceed 1 l/day. Thus, under normal living conditions in the north temperate zone, the loss of iron in perspiration is negligible and probably does not exceed 0.02 to 0.06 mg/day. The possibility that perspiration contains no iron can not be ignored. In 3 of the 19 samples collected from the 5 subjects no iron was present.

Color measurement in products of rice milling MARINUS C. KIK, *Univ. of Arkansas, Fayetteville, Ark.* Whole kernel samples of mill products (brown, first break, second break, and head or white rice) of Blue Rose, Zenith, California Pearl and Nira, tested for color with the Hardy self-recording photoelectric spectrophotometer, gave average percentage reflectances at 460 m μ and at 660 m μ for brown rice, 25 and 51, for first break, 33.6 and 59.2, for second break, 36.2 and 61.3 and for head rice, 36.1 and 60.6. In the whole visible region (especially in the yellow), reflectance values between brown and white rice differed considerably, were small between first break and nonappreciable between second break and white. The photovolt photoelectric reflectometer, with blue, green and red filters, gave similar results. Blue and green filters were more effective than the red filter. In these latter studies rice samples with different bran removal (1 to 10%) were tested for color. The widest spread of readings between samples of one variety is obtained when measurements are made with 'suppressed zero'. Using the blue filter and for brown rice a setting at 0, gave readings for first break, second break and head rice of 50, 58 and 69 respectively. The results of these reflectometer studies might find application in government grading, in description of standards for rice and in controlling rice milling to a specific degree of whiteness.

Pteroylglutamic acid studies on patients with tropical sprue Factors affecting urinary excretion levels. ELIZABETH M. KNOTT and RAMÓN M. SÁENZ (introduced by R. R. WILLIAMS), *School of Tropical Medicine, San Juan, Puerto Rico*. The urinary excretion of pteroylglutamic acid has been assayed with Lactobacillus casei, for 313 24-hour specimens and 237 2-8-hour collections, from 65 individuals. Patients with tropical sprue were diagnosed in accordance with the criteria defined by

Suárez, et al (*Ann Int Med* 26 643, 1947) Results are reported as micrograms The average total daily excretion for sprue patients was 1 109 (range for 6 patients 0 166–0 778, and 4 patients 1 180–3 068) Eight staff members averaged 1 693 (range 0 920–4 100) Two non-sprue, anemic patients excreted 0 418 and 0 243 on a low protein diet, increased to 0 650 and 0 433 when niacin was added, and increased to 1 544 and 1 273 when given the regular hospital diet Three anemic patients on a diet high in protein and vitamins, plus injections of liver extract, excreted an average of 4 340 (range 3 909–4 715) The night rate of excretion, in $\mu\text{g/hr}$, was 0 022 for sprue patients, 0 057 for other hospital patients, and 0 076 for staff members During fasting in the morning, the rate of excretion decreased for sprue patients to 0 016, but increased to 0 094 and 0 119 for the other hospital patients and staff members One staff member, although receiving an excellent diet, excreted amounts of pteroylglutamic acid comparable to the lower figures for sprue patients, and had a tendency for repeated episodes of a spruelike syndrome Women during the last trimester of pregnancy had night excretion rates of 0 068 and fasting rates of 0 101, but decreased to 0 049 and 0 091 during the first week postpartum

Paradoxical relationship between serum level and liver content of vitamin A R F KRAUSE (introduced by H B PIERCE) *Dept of Biochemistry, College of Medicine, Univ of Vermont, Burlington, Vt* An examination has been made of the relationship between serum level and liver content of vitamin A in normal rats and those under the influence of varying degrees of vitamin-A depletion An inverse relationship has been found between the blood and liver levels of vitamin A in normal rats and in depleted animals whose liver content ranged as low as 600 IU /total liver However, under conditions of more severe depletion when the total liver content fell below 600 IU , there was a parallelism between blood and liver levels This evidence supports the hypothesis that there is a regulatory mechanism controlling blood vitamin-A levels of the rat which, under the conditions described above, operates to give an inverse relationship between blood level and liver content of vitamin A This mechanism, however, fails to function under conditions of extreme depletion

Some inter-relationships of thiamine and fat in the nutrition of the rat M M KRIDER (by invitation) and N B GUERRANT *Dept of Agricultural and Biological Chemistry, Pennsylvania State College, State College, Penna* Studies, with regulated intakes of isocaloric diets, designed to clarify the probable inter-relationship of the thiamine and fat intake of the rat and the amounts of thiamine and fat stored in the rat's body have yielded data that permit the following conclusions 1) Increasing the thiamine intake from 2 to 1000 μg daily had less

effect on increasing the body-weights of rats than did increasing the fat content of the diet from 0 to 20% This increase in body-weight was due primarily to greater fat deposition attained by the rats receiving the fat-containing diets 2) The cardiac thiamine of rats was found to depend primarily on the thiamine intake and was not markedly affected by the fat content of the diet 3) Under the conditions of the experiments, the fat content of the rat's body was found to increase with the fat content of the diet and was not markedly influenced by the thiamine intake where the intake of this vitamin was 50 μg or more/day 4) The index of refraction of the body fat of rats was found to vary with the fat (Crisco) content of the rat's diet and to decrease with an increase in the amount of fat present in the rat's body

Effect of dietary restriction and rehabilitation upon the spontaneous activity of rats HARRY KRZYWICKI and ESTHER DA COSTA (introduced by ROBERT E JOHNSON) *U S Army Medical Nutrition Laboratory, Chicago 9, Ill* During an average of 14 weeks, a control group of 12 male rats fed ad libitum gained 121% in weight with an average food intake of 14 9 gm/rat/day and showed an average activity of 1101 rotary cage revolutions/ rat/day Eighteen rats fed a quantitatively restricted but otherwise complete diet lost 42% in weight with a food intake of 8 gm/rat/day and an average activity of 7854 cage revolutions/ rat/day The peaks in activity of the restricted rats occurred during the 6th, 9th and 10th weeks Six rats fed 8 gm/rat/day of a low protein, high salt diet lost 32% in weight and showed an activity of 3351 cage revolutions/ rat/day During dietary rehabilitation, spontaneous activity decreased promptly and showed an average of 1143 revolutions/ rat/day with a high fat diet, 1176 revolutions/ rat/day with a high carbohydrate diet and only 640 revolutions/ rat/day for a high protein diet Thus both types of food restriction caused increased activity but different types of refeeding led to significantly different reductions of spontaneous activity

Nitrogen excretion of women related to the distribution of animal protein in the daily meals RUTH M LEVERTON and MARY R GRAM (by invitation) *Human Nutrition Research Laboratory, Univ of Nebraska, Lincoln, Neb* This study is a preliminary investigation of whether the time element in the feeding of complete proteins affects the utilization of the nitrogen by human subjects Fourteen college-age girls were kept on a constant diet which furnished 62 gm of protein daily for 36 days During the first 18-day period a fruit-bread products-coffee breakfast, which furnished no protein from animal sources, was served and all of the animal protein was given in the noon and evening meals During the second 18-day period a glass of milk was taken from the evening meal and added

to the breakfast. Metabolism data were secured on all subjects for the last 9 days of each of the 2 periods. The average daily excretion of nitrogen for all subjects for the first and second periods was 9.07 and 8.57 gm respectively for urinary nitrogen, and 0.57 and 0.54 gm respectively for fecal nitrogen. Differences between daily nitrogen excretion of the 2 periods were not always statistically significant. On the same level of protein intake there was, however, a persistent trend toward a lower nitrogen excretion when the animal protein from a glass of milk was in the breakfast than when the animal protein was present only in the noon and evening meals. All subjects were in nitrogen equilibrium during the first period and retained an average of 1.03 gm nitrogen daily during the second period.

Studies involving protein stores in man. STANLEY LEVEY, JOHN E. HARROLD and CHARLES J. SMITH (introduced by ARTHUR H. SMITH). *Wayne County General Hospital, Eloise, Michigan, and the Depts. of Physiological Chemistry and Medicine, Wayne Univ. College of Medicine, Detroit, Mich.* The plasma volume (dye method), total circulating proteins and albumin were determined before and 30 minutes after the infusion of 1000 ml of physiological saline in 4 normal, healthy males and in 6 male patients exhibiting various degrees of undernutrition. The undernourished subjects were then placed on a high caloric (4000-5000), high protein (2.0 to 4.0 gm/kg/day) diet for a period of at least 3 weeks after which the above procedure was repeated. The subjects with normal nutrition demonstrated a constant response to the saline infusion characterized by an increase in plasma volume, approximately 350 ml, a decrease in serum protein concentration, but an increase in total circulating proteins. The albumin changes did not follow a consistent pattern. The response to the saline infusion exhibited by the malnourished patients was characterized by decrease in both the protein concentration and in the total circulating proteins, in spite of an increase in plasma volume. The malnourished subjects who were followed through the controlled dietary period demonstrated an increase in circulating proteins after the saline infusion similar to the normal controls. The major interest of this study centers on the changes in the circulating proteins following the saline infusion. The increase in circulating proteins demonstrated by the normal patients is explained by a washing into the circulation of proteins from a labile protein store. The decrease in circulating proteins exhibited by the undernourished patients is explained by a lack of labile protein stores. The change from the malnourished to the normal pattern after the period of dietary treatment demonstrates the repletion of the protein stores.

Human urinary and fecal elimination of vitamin B₆ and 4-pyridoxic acid on a controlled diet

HELEN LANKSWILER and MAY S. REYNOLDS (introduced by HELEN T. PARSONS). *Dept. of Home Economics, Univ. of Wisconsin, Madison, Wis.* The pyridoxine intake and the pyridoxine and 4-pyridoxic acid elimination by 12 normal human subjects on a controlled dietary intake have been determined. The diet furnished from 0.5 to 1.0 mg of B₆ and from 19 to 32 gm vegetable protein per day by analysis. Supplements of thiamine, riboflavin, niacin and calcium lactate were given. Calories were adequate to maintain weight. A period of 9 days with no pyridoxine supplement was followed by a 9-day period during which 15 mg pyridoxine per day were given. In the first period, the pyridoxine and 4-pyridoxic acid eliminated ranged from 0.85 to 3.7 mg in excess of the pyridoxine intake. 4-pyridoxic acid accounted for approximately 80% of this total excretion. Intestinal synthesis of B₆ in man has been assumed by other investigators but has not been previously demonstrated. Studies of the effect of sulfasuxidine on synthesis are in progress. When the diet was supplemented with 15 mg of pyridoxine HCl daily only 50 to 60% of the total intake was eliminated. 4-pyridoxic acid excretion during this period ranged from 75 to 80% of the total metabolites determined.

Age and calcium utilization. C. M. MCCAY, F. E. LOVRIER (by invitation), C. H. LEE (by invitation) and G. KALL (by invitation). *Laboratory of Animal Nutrition, Cornell Univ., Ithaca, N. Y.* Rats, starting at 38 days of age stored 90% of the calcium from a diet containing 0.3% Ca, until the animals were 110 days old. At 160 days of age these rats stored 55-65% of the Ca. Littermate rats fed a similar diet containing enough oxalate to tie up $\frac{1}{3}$ of the dietary Ca stored only the free Ca until 70 days of age. After this age the utilization improved until 80% of all dietary Ca was stored at 100 days of age. After this Ca storage was only 10% below the controls in spite of the presence of oxalates. If oxalates were fed with meat in the morning and calcium fed as milk 5 hours later, the utilization of Ca was improved during the months shortly after weaning, when assimilation of Ca was difficult. Analogous studies with young puppies gave similar results. In order to determine the effect of the lipids of the diet upon the wastage of dietary calcium in old rats, balances were run upon animals ranging from 450 to 900 days of age. On a weight basis the fat in the diet was varied from 2 to 30%. Under conditions of a constant but marginal daily intake of Ca, the higher fat levels created a greater negative balance. A similar effect was found when the percentage of Ca in the diet was kept constant but the Ca ingested was increased, due to the consumption of more of the low fat food.

Effect of carbohydrate on the nutritive value of heated protein. IVAN J. MADER (by invitation), LAWRENCE J. SCHROEDER (by invitation) and

ARTHUR H SMITH *Dept of Physiological Chemistry, Wayne Univ College of Medicine, Detroit, Mich* A nitrogen balance study was used to determine the possible role of carbohydrate in altering the nutritive value of heated protein. A synthetic diet containing all the known dietary essentials was fed to three adult female dogs. Commercial and 'carbohydrate-free' lactalbumin, heated under various conditions, served as the protein nitrogen sources. All diets fed were isocaloric and daily nitrogen intakes kept at a constant minimal level for each dog. Based on the partition of nitrogen excretion between the urine and feces, no changes in digestibility or nutritive index occurred when the protein was dry-heated at 120°. Using the original lactalbumin as a criterion, significant decreases in both digestibility and nutritive value did occur when the lactalbumin was autoclaved. This decrease in nutritive value was proportional to the severity of heat treatment. Commercial lactalbumin contains large amounts of reducing substances, chiefly lactose. Water extraction allowed almost complete removal of the carbohydrate. The extracted lactalbumin, heated in the same manner as the commercial lactalbumin, was fed in another series of experiments. After removal of the carbohydrate, an increase was observed in both the digestibility and nutritive index of the autoclaved protein. The extracted lactalbumin was reconstituted with lactose with respect to the carbohydrate content of the original protein. Upon heating, the carbohydrate content diminished and severe negative nitrogen balances resulted. Decreased digestibility of the autoclaved lactalbumin, as evidenced by increased fecal nitrogen, accounted for the decrease in its nutritive value. Utilization of absorbed nitrogen remained uniformly high in all cases.

Effect of various degrees of starvation on gonadotrophic and lactogenic content of rat pituitaries **JOSEPH MEITES** and **J O REED** (introduced by **C F HUFFMAN**) *Dept of Physiology and Pharmacology, Michigan State College, East Lansing, Mich* Five groups each of intact and ovariectomized mature rats were put on full, $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$ and no-feed regimes. The first 4 groups were killed at the end of 14 days and the 5th group at the end of 7 days. Pituitary gonadotrophic content was determined by injecting an aqueous aliquot of 5 pituitaries from each group into 5 immature female rats during a 5-day period, and weighing the ovaries and uteri on the 6th day. Lactogenic potency was measured by injecting an aqueous aliquot of 2 pituitaries from each group intradermally over the crop glands of 5 pigeons during a 4-day period, and rating the crop responses on the 5th day. Regardless of the degree of starvation in either intact or ovariectomized rats, there was no reduction in pituitary gonadotrophic content. This occurred

despite the marked atrophy of the ovaries and uteri of the intact rats, and the high initial pituitary gonadotrophic content of the ovariectomized rats. Pituitary lactogenic potency was reduced in both intact and ovariectomized rats on the $\frac{1}{2}$, $\frac{1}{3}$ and no-feed regimes, corroborating the report of Meites and Turner (*Mo Agr Exper Sta Res Bul* 416, 1948) that mother rats starved during lactation show a decrease in pituitary lactogenic content. It is concluded that during starvation, pituitary gonadotrophic content is not and pituitary lactogenic content is an accurate index of the amount of hormone released into the blood stream.

Folic acid deficiency and the respiration and pyruvate utilization of duckling erythrocytes and cardiac muscle **O NEAL MILLER** (by invitation), **ROBERT E OLSON** (by invitation) and **FREDRICK J STARE** *Dept of Nutrition, Harvard School of Public Health, and Dept of Biological Chemistry, Harvard Medical School, Boston, Mass* Folic acid deficiency was induced in 4-day-old white Pekin ducklings by feeding a purified diet supplemented with sulfaguanidine. After the onset of anemia, the deficient birds were taken for respiration studies by the direct method of Warburg. Controls fed the deficient diet plus folic acid were tested simultaneously. Blood was drawn from the jugular vein into heparinized syringes, centrifuged, and washed once with cold phosphate-saline at pH 7.4. Slices of heart ventricle from the same birds were prepared. The washed red cells and the cardiac muscle slices were then incubated at 37°C for 1 hr after equilibration in an atmosphere of oxygen. When pyruvate was added as substrate, it was initially present in the medium. The disappearance of pyruvate and formation of lactate was determined chemically and the net pyruvate utilization, i.e., the conversion of pyruvate to non-lactate products, calculated. Data obtained with heart muscle slices are expressed in terms of (Q) while that obtained with the red cell suspensions are expressed in terms of microliters of substrate or oxygen utilized per ml of standard blood (hematocrit = 38). Slices of ventricle from folic acid deficient ducks showed no depression in oxygen consumption below that of controls either with added pyruvate ($QO_2 = 12$) or without pyruvate ($QO_2 = 9$). The conversion of pyruvate to lactate, however, was increased, and the conversion of pyruvate to non-lactate products was decreased approximately 20% by the deficiency. The erythrocytes from deficient birds showed a decrease in both respiration and pyruvate utilization.

Fate of ascorbic acid, dehydroascorbic acid and diketogulonic acid in the animal body **MARY B MILLS** (by invitation), **CHARLOTTE M DAMRON** (by invitation) and **JOSEPH H ROE** *Dept of Biochemistry, School of Medicine, George Washington Univ, Washington, D C* Normal guinea

pigs maintained on a stock diet supplemented with cabbage were injected or fed by stomach tube with pure solutions of ascorbic acid, freshly prepared dehydroascorbic acid, or a calcium diketogulonate. After 1 or 2 hours, the animals were sacrificed and the various tissues analyzed for ascorbic acid, dehydroascorbic acid, and diketogulonic acid. Ascorbic acid was recovered as such to the extent of about 40-50% of the amount administered. Dehydroascorbic acid was recovered to about 30-40% of the amount given and some was reduced to ascorbic acid or converted to diketogulonic acid in the animal body. Diketogulonic acid was recovered to about 25-30% of the amount given and there was no evidence of transformation to the other two compounds being analyzed. Young guinea pigs about 50-100 gm in size were used as a check upon the total recoveries obtained with adult pigs. The animals were injected with the test compound and killed 1 or 2 hours after injection. The animal was skinned and the carcass was ground into a slurry in the Waring blender under 10% stannous chloride solution containing CO_2 . The slurry was made to a satisfactory volume with 5% H_2PO_4 and analyzed for total ascorbic, dehydroascorbic and diketogulonic acids. Recoveries were a little higher with ascorbic and dehydroascorbic acids, and a little lower with diketogulonic acid, than those obtained with adult animals. The data obtained with young guinea pigs confirmed the observations on the fate of the three compounds in adult animals.

Essentiality of vitamin B_{12} for the baby pig, with preliminary quantitative data. A. L. NEUFMANN (by invitation), MARIAN F. JAMES (by invitation), J. L. KRIDER (by invitation) and B. CONNOR JOHNSON, *Dept. of Animal Science and Division of Animal Nutrition, Univ. of Illinois, Urbana, Ill.* Isolated soybean protein 'synthetic milk' fed to baby pigs was improved by supplementation with a vitamin B_{12} concentrate, both from the standpoint of growth and of physiological well-being. Forty-two micrograms of vitamin B_{12} /kg dry matter in the diet produced the maximum growth response and improved hematopoiesis. Grossly, the vitamin B_{12} deficient pigs were extremely irritable, sensitive to touch, sluggish in their movements, and a number of the pigs were unable to stand upon their rear legs. All the vitamin B_{12} pigs on the two highest levels fed grew better and showed none of the above symptoms. One group fed a manure factor concentrate showed the same gross symptoms as the vitamin B_{12} deficient pigs but grew almost as rapidly as those fed the higher levels of vitamin B_{12} . Hematopoiesis was rather severely strained in all the pigs fed the B_{12} deficient diets as well as in those fed the manure factor, as indicated by bone marrow and blood studies, even though 0.4 gm pteroylglutamic acid

was included per kg dry matter in the diet. Histological information on the nerves, gastro intestinal tract and other organs will be presented, as well as data on the blood and bone marrow condition. The growth effect of the injection of crystalline vitamin B_{12} in baby pigs fed the same basal diet will also be reported as well as some preliminary data on a pteroylglutamic acid vitamin B_{12} relationship.

Biochemical studies on primigravidae on self-selected diets differing greatly in nutritive value. HILLY OGDEN, BLANCIE BLUM-SHIFT (by invitation) and THIRMA PORTER, *Dept. of Home Economics, Univ. of Chicago, Chicago, Ill.* Primigravidae, living at home on self-selected diets, were studied for 10 day periods during each of the last 5 months of pregnancy. All food eaten during the first 7 days of each period was weighed and samples were saved for thiamine, riboflavin, niacin, nitrogen and tryptophane analyses. Intakes of other nutrients were calculated. Complete collections of excreta were made during the 7 days and aliquots analyzed. On the 7th, 8th, 9th and 10th days, after identical breakfasts, 1 hour urine specimens were collected. That on the 7th day served as a control and those on the 8th, 9th and 10th days as a measure of riboflavin, niacin and thiamine test doses, respectively, which were given with breakfast. The average daily intakes of the different subjects ranged as follows: calories, 400 to 2300, protein, 10 to 100 gm, Ca , 0.1 to 2.7 gm, iron, 4 to 150 mg, vitamin A, 600 to 16,600 IU, vitamin D, 500 to 3000 IU, ascorbic acid, 6 to 160 mg, thiamine, 0.35 to 19 mg, riboflavin, 0.23 to 20 mg, niacin, 4 to 86 mg. High intakes of vitamins and minerals were due for the most part to voluntary supplementation, the low, to poor dietary habits. The proportion of the thiamine intake which was excreted was relatively constant whereas that of riboflavin varied directly with the intake. Test dose returns of both thiamine and riboflavin were very low on low intakes. Excretion of niacin metabolites on low intakes usually exceeded the amount of niacin ingested, sometimes by as much as 100%. Niacin test dose returns of these subjects also tended to be high. Consistently negative nitrogen balances were found only when the average daily protein intakes were less than 30 gm.

Metabolism of radioactive acetate and pyruvate by cardiac muscle from normal and pantothenic acid-deficient ducklings. ROBERT E. OLSON (by invitation) and FREDRICK J. STARE, *Dept. of Nutrition, Harvard School of Public Health, and Dept. of Biological Chemistry, Harvard Medical School, Boston, Mass.* Acetate labeled in the carboxyl with C^{14} and 2 isomers of pyruvate, labeled respectively in the carboxyl group and the alpha carbon atom were synthesized. Slices and dilute homogenates of heart ventricle from normal and

pantothenic acid-deficient ducklings were incubated with these substrates in Warburg flasks. The gas phase in the slice experiments was O_2 , in the homogenates, air. Total pyruvate disappearance and lactate appearance were determined chemically and the conversion of pyruvate to non-lactate products expressed as net $-Q_{\text{pyruvate}}$. The rate of oxidation of the labeled carbon atom in the respective substrates was determined by counting the $C^{14}O_2$ trapped in the center well. All substrates were tipped in from side arms after equilibration and gave a final concentration of 5 mM/l. The following representative data were obtained in a series of normal ducklings

	Net -Q Pyruvate	$QC^{14}O_2$ Pyruvate Car- boxyl	$QC^{14}O_2$ Pyruvate α -carbon	$QC^{14}O_2$ Acetate Car- boxyl
Slice	5.2	2.8	1.8	1.1
Homogenate	3.8	3.7	2.2	0.7

These data indicate that in the slice, but not in the homogenate, considerable amounts of added pyruvate are metabolized to non-lactate products without the loss of CO_2 . The oxidation of added pyruvate in slices of ventricle from pantothenic acid-deficient ducks was essentially normal. In homogenates of deficient ventricle, however, there was a marked depression in pyruvate oxidation. The oxidation of the alpha-carbon atom was reduced more than the rate of decarboxylation. The oxidation of acetate was reduced in both slices and homogenates.

Relationship of riboflavin deficiency to adrenicortical function as shown by carbohydrate metabolism in anoxia. BLUEBELL READE (by invitation) and AGNES FAY MORGAN *Laby of Home Economics, Univ of California, Berkeley, Calif*. Young rats were subjected fasting to anoxic anoxia after 1, 3, 5, 8 and 12 weeks on riboflavin-deficient diet. After the test period of 24 hours, blood sugar, liver glycogen and muscle glycogen were determined. Comparable animals kept at sea-level under the same conditions were similarly examined, as were rats given the same diet plus riboflavin under anoxia and at sea-level. The total carbohydrate content of the deficient animals was greater than that of those on normal diet through the third week but this decreased rapidly below the normal fasting level in the 5th to the 12th week. Injection of 0.1 mg riboflavin immediately before, or of 2 ml cortin in the 24 hours just preceding the test period, restored the carbohydrate-producing capacity of the deficient rats. Injection of desoxycorticosterone, 5 mg in oil, in the 48 hours preceding the test had little effect. Adrenalectomized rats on the control diet were not enabled to increase their carbohydrate content by injections of

0.1 mg riboflavin. Pair-fed normal controls exhibited increased gluconeogenetic capacity above that of the full-fed positive controls. The behavior of the deficient animals corresponded with that described by Selye as 'alarm reaction' during the first part of the deficiency and 'collapse' in the latter part. This may indicate that the state of riboflavin deficiency involves increased adrenicortical activity at first followed by adrenal cortex exhaustion. Either the complete cortical extract, cortin, or riboflavin substituted for, or restored adrenicortical function.

Relation of age to ascorbic acid metabolism in guinea pigs. MARY ELIZABETH REID *Expt'l Biol and Med Inst, N I H, Bethesda, Md*. Two groups of inbred male guinea pigs, one slightly over 2 months of age and the other ranging from 1 to over 3 years, were fed a commercial pelleted diet, supplemented with 1% of powdered yeast, vitamin E, and a small amount of fresh carrots. Daily intraperitoneal injections of ascorbic acid (5 mg/100 gm) were given for at least 3 weeks before the experiments were made. At periods varying from $\frac{1}{2}$ to 24 hours after the usual daily injection, blood samples were taken, following which the animal was killed. The liver, kidneys, spleen, adrenals, and the contents of the gastrointestinal tract were removed, assayed for ascorbic acid and the responses of the young and old groups to the experimental procedure were compared. The basal, pre-injection levels in the blood and liver were found to be lower in the young animals. Following administration of the vitamin, the levels in both groups rose rapidly in the blood, kidneys, and liver but showed no consistent variations in the adrenals and spleen. The rapidity of increase and the subsequent return to basal levels varied from organ to organ. The young animal showed a more rapid increase in the liver content but it also decreased earlier. The kidneys of the young animal maintained a high level much longer than the older group suggesting the possibility of greater tubular reabsorption. Assay of the contents of the digestive tract yielded no evidence of more rapid excretion and destruction in the younger group. It is known that the dietary requirements of vitamin C for young and old animals is approximately the same per unit of weight. However, these present results together with the results of earlier studies suggest that the younger animal actually stores and uses more vitamin C than the older animal. The evidence indicates that there is greater wastage in the older animals.

Germ-free chick nutrition development on synthetic-type diets. J. A. REYNIERS (by invitation), T. D. LUCKEY (by invitation), P. C. TREXLER (by invitation), R. F. ERVIN (by invitation), M. WAGNER (by invitation), H. A. GORDON (by invitation) *Germ-Free Life Division, LOBUND,*

Notre Dame, Indiana, R A BROWN, G J MAN-
NERING (by invitation) and C J CAMPBELL (by
invitation) *Research Labys, Parke, Davis & Co,*
Detroit, Mich The role of intestinal micro-
organisms in nutrition research is of considerable
theoretical and practical importance. Attention has
been largely directed toward the possible synthesis
of vitamins by the intestinal flora. This report
records a study to determine whether germ-free
chicks require a dietary source of unknown vita-
mins. Chicks were obtained and reared germ-free
according to the method of Reyniers *et al*
(LOBUND Reports, No 2). The animals were
fed autoclaved water and synthetic-type diets
(with and without liver and yeast) for 4 to 9 weeks.
Bacteriological tests (microscopic and cultural)
showed the chicks to be free from all demonstrable
living microorganisms. The diets used were ade-
quate as shown by chemical and biological methods.
The percentage of nutrients lost during auto-
claving at 122°C for 25 minutes is as follows:
thiamin, 90, riboflavin, 15, niacin, 3, pantothenic
acid, 45, pyridoxine, 31, biotin, 0, choline, 12,
folic acid, 64, vitamin A, 19, vitamin E, 46, vita-
min K, 38, lysin, 0, tryptophane, 8. Feather de-
velopment was excellent in the germ-free chicks.
When 4 weeks old, they were somewhat heavier
than the control chicks fed the same diet in 4 of
7 experiments. The presence of liver and yeast
powder or fresh liver extract did not significantly
increase growth rate or hemoglobin formation.
Hematopoiesis was normal except for some devia-
tions in the white blood cell picture. Perosis oc-
curred in some of the germ-free birds. The results
indicate that the nutritional requirements of germ-
free chicks are similar to those of the controls.
Therefore if the search for unknown vitamins is to
be carried further, it is evident that either the
diets or the animals used will have to be changed.

Amino acids and vitamin B₁₂ as supplements to
plant proteins for growing chicks. L R RICHARD-
SON, L G BLAYLOCK (by invitation), H L
GERMAN (by invitation) and R M SHERWOOD
(by invitation) *Texas Agricultural Experiment*
Station, College Station, Texas Amino acids and
vitamin B₁₂ were investigated as supplements to
commercial cottonseed meal low in gossypol and
to soybean meal for growing chicks. The protein
concentrates were added in quantities to supply a
total of 20% protein in the diet. One typical diet
contained corn meal, protein concentrate, steamed
bone meal, manganese sulfate and all vitamins re-
quired by growing chicks. Another contained cere-
lose instead of grain and mineral mixture instead
of bone meal. The experimental period was 4 weeks.
Chicks receiving the corn cottonseed meal diet
weighed an average of 150 gm while those receiving
the same diet plus 0.5% of L(+) lysine weighed
250 gm. When the basal diet contained 3% sardine

meal the chicks weighed an average of 206 gm
without and 252 gm with lysine. The further addi-
tion of 0.1% of DL tryptophan and 0.2% of DL-
methionine to the cottonseed meal sardine meal
diet increased the weight to 282 gm. A vitamin B₁₂
concentrate was investigated as a supplement to
cottonseed and soybean meals. Three chicks re-
ceiving a cerelese cottonseed meal diet supple-
mented with 0.8% of DL-lysine in addition to
tryptophan and methionine weighed an average of
228 gm while 3 receiving the same diet plus 40
Mcg/kg of vitamin B₁₂ weighed an average of
300 gm. Two groups of 17 chicks each receiving
the cerelese soybean meal diet weighed an aver-
age of 250 gm without and 285 gm with vitamin
B₁₂.

Metabolism of p-aminobenzoic acid and some
of its conjugates by the rat. THOMAS R RIGGS
(by invitation) and D MARK HEGSTED *Dept of*
Nutrition, Harvard School of Public Health, Dept
of Biological Chemistry, Harvard Medical School,
and Dept of Biochemistry and Nutrition, Tufts
College Medical School, Boston, Mass The acetyla-
tion of p-aminobenzoic acid (PAB) in rats has been
shown to be diminished in pantothenic acid de-
ficiency (*J Biol Chem* 172: 539, 1948) and also to
be influenced by deficiencies of thiamine and ribo-
flavin and by the amount of PAB administered
(*J Biol Chem* in press). Since PAB can be con-
jugated at the carboxyl group (with glycine) as
well as at the amino group, it appeared that the
extent of acetylation of the amino group would
probably be influenced by the extent of conjuga-
tion of the carboxyl group. Determinations of
PAB, p-aminohippuric acid (PAH), and their
respective acetyl derivatives were carried out on
the urines collected for 24 hours after intraperi-
toneal injection of various amounts of these
compounds. Results showed interconversion among
the 4 substances, so that all four appeared in vary-
ing proportions after PAB, PAH, or acetyl-PAH
were injected. No acetyl-PAH was found after
acetyl-PAB was given. The latter observation in-
dicated that conjugation at the carboxyl end was
prevented once conjugation had occurred with the
amino group. Whenever the extent of acetylation
of PAB was diminished by nutritional deficiency
or by increasing the dose, conjugation at the car-
boxyl group was reciprocally increased so that the
total proportion conjugated at one position or the
other remained constant. The extent of acetylation
as affected by pantothenic acid deficiency and by
glycine supply (modified by preadministration of
benzoic acid or of glycine) has been studied after
administering PAB, PAH, and sulfanilamide.

Availability of pantothenol and calcium panto-
thenate in relation to food intake. S H RUBIN,
L DREKTER (by invitation), M E MOORE (by
invitation) and R PANKOFF (by invitation)

Nutrition Laboratories, Hoffmann-La Roche Inc., Nutley, N J Previous work in this laboratory (*J Nutrition* 35 499, 1948) has indicated that the availability of calcium or sodium pantothenate to humans at elevated dosage levels is depressed by food intake to a considerably greater extent than is that of panthenol. Further study of this effect in rats by an excretion technique (*J Am Pharm Assn* 37 498, 1948), at dosage levels within the linear working range of 1 to 10 mg/kg permits the following conclusions to be drawn: 1) During *ad libitum* feeding, panthenol is approximately 200% (range 193-267%) as available as equivalent amounts of calcium pantothenate at all doses fed (A value of 100% denotes equal availability). 2) Starvation for 24 hours (postabsorptive state) enhances the absolute urinary excretion of pantothenic acid in response to the 'loading' test doses at all levels, especially after calcium pantothenate. 3) The relative availability of panthenol and calcium pantothenate in this postabsorptive state is of the order of 220, 140 and 116% at the respective dosage levels of 10, 5 and 2 mg/kg. 4) In contrast with Silber's results with calcium pantothenate in dogs (*Arch Biochem* 7 329, 1945), the post-absorptive urinary responses are not profoundly affected by the administration of food with the dose. However, a significant increase in fecal pantothenic acid does occur when 10 mg/kg of calcium pantothenate is given with food, but not with 5 or 2 mg/kg. These results confirm and extend the previous findings in humans that the availability of panthenol is better than that of calcium pantothenate under conditions of higher dosage and *ad libitum* feeding, and is more nearly equal in the postabsorptive state at lower doses.

Vitamin A requirement of the turkey poult fed a purified diet WALTER C RUSSELL, M WIGHT TAYLOR and ROBERT VAN REEN (by invitation) *Dept of Agricultural Biochemistry, New Jersey Agr Exp Sta, Rutgers Univ, New Brunswick, N J* Poults fed a purified diet in which protein was supplied as casein and gelatin and vitamin A as the acetate, required at least 3000 IU of the vitamin per kg of diet (1360 IU/lb) for normal growth. 5000 IU/kg of diet (2270 IU/lb) was required to prevent all external signs of the deficiency, such as ruffled plumage, staggering gait, and cloudiness of the inner eyelid. After 6 weeks on experiment, no liver storage was found even at a level of 6000 IU/kg of diet (2720 IU/lb). In all of the groups receiving the purified diet, the lining of the esophagus and crop presented a white furrowed appearance. Histological studies showed the development of very large cells in the epithelial layer with considerable exfoliation. It is not known whether this condition was the result of inadequate vitamin A or due to the physical character of the purified diet. On a practical mash the furrowed condition did not occur. For normal growth and

external appearance, 5000 IU of vitamin A per kg of diet (2270 IU/lb) are considered adequate.

Metabolism of tryptophan labeled with radioactive carbon DATTAREYA RAO SANADI (by invitation) and DAVID M GREENBERG *Division of Biochemistry, Univ of California Medical School, Berkeley, Calif* DL-tryptophan (200 mg) labeled with C^{14} at the beta-carbon was administered subcutaneously to rats made diabetic with phlorhizin. From the subsequent 24-hour urine collection, glucose was obtained as the phenylglucosazone which was then converted to the phenylglucosotriazole by treatment with cupric sulphate. The ketone bodies were obtained first as the mercury acetone complex and then as 2,4-dinitrophenylhydrazone. The glucose exhibited radioactivity but the acetone was inactive. The activity in the CO_2 , obtained by treating the urine with urease, was too low to explain the activity in the glucose as being entirely due to CO_2 fixation. Upon degrading the glucosotriazole by oxidation with sodium periodate it was found that approximately one-fourth of the activity of the glucose molecule was in carbon 6 and another one-fourth in carbons 4 and 5. From the present knowledge of the products of tryptophan metabolism and from the isotopic distribution in glucose it appears that a two carbon unit with C^{14} in the alpha-position is formed from tryptophan and is incorporated in the tricarboxylic acid cycle directly, but this two carbon unit does not form acetoacetate in the diabetic animal. Oxidative deamination and subsequent oxidative decarboxylation of kynurenine would yield the compound $NH_2 \cdot C_6H_4 \cdot CO \cdot C^{14} \cdot H_2 \cdot COOH$. In the phlorhizinised animal, this compound may break down to anthranilic acid and a two carbon derivative. The formation of such a derivative has been confirmed by giving a normal rat $10 \mu c$ (about 12 mg) of the radioactive tryptophan together with p-amino-benzoic acid. The excreted p-acetylamino-benzoic acid was radioactive.

Vitamin nutriture and tryptophan metabolism in man HERBERT P SARETT and GRACE A GOLD-SMITH *Nutrition Research Lab, Tulane Univ School of Medicine, New Orleans, La* Further studies have been conducted on the excretion of nicotinic acid and tryptophan compounds by subjects maintained on a wheat diet, which provides about 40 gm of protein and 6 mg of nicotinic acid per day (*J Biol Chem* 167 293, 1947). The addition of DL-tryptophan to this diet leads to an increase in excretion of N'-methylnicotinamide which is not affected by supplementing the diet with 50 mg of nicotinamide per day or with a combination of the other B vitamins. The high level of nicotinamide does not decrease the conversion of tryptophan to nicotinic acid compounds. The addition of DL-tryptophan to the diet leads to an increased excretion of two other compounds, one has tryptophan-like activity for *Lactobacillus*

containing ethanol extracted casein (55-60°C for 72 hours) in place of the soybean protein and methionine but otherwise the same components. These rats were bred and their young were fed the soybean ration. On the soybean ration the 6 weeks post weaning weight gains were for the parent generation, males (12) 172 gm \pm 15.4 (SD), females (26) 123 gm \pm 8.4, for the F₁ generation males (31) 175 gm \pm 13.6, females (32) 112 gm \pm 12.5, not significantly lower than those on a casein containing ration. To date from 46 pregnancies there were 3 probable resorptions and 43 litters with 14 dead and 263 live young. Of the latter 14 whole litters and 101 young failed to survive the third day after birth. Of 162 rats surviving the third day, 153 (94.4%) were weaned at 21 days with a mean weight of 35.6 gm. The cause of the high early mortality is not known but in no case could it be ascribed to failure of the young to obtain sufficient milk since lactation performance in all cases was excellent.

Nutrition of women during normal and abnormal pregnancy in Panama and the Canal Zone. NEVIN S. SCRIMSHAW (by invitation), MARTHA J. THOMASON (by invitation), ROBERT P. BAYS (by invitation) and ESTELLE E. HAWLEY. *Dept. of Obstetrics and Gynecology, Univ. of Rochester, School of Medicine and Dentistry, Rochester, N. Y.* The dietary intake of 308 pregnant women representing 5 distinct economic or racial groups in Panama and the Canal Zone was studied by diet interviews. The incidence of pre-eclampsia for each of these groups in over 12,000 deliveries did not indicate a true tendency for this condition to occur more frequently in groups with a lower average nutritional intake. Furthermore, when the diet histories of 75 women with pre-eclampsia were analyzed, there was no reasonable statistical possibility that their diets were poorer than those of their own racial or economic group in general. Blood samples from 242 pregnant women representing the above 5 groups and 2 interior villages were analyzed for total protein, vitamin A, carotene, free and total riboflavin and alkaline phosphatase. Alkaline phosphatase showed little variation with diet and economic status, increased with gestation, and appeared to be lower in the white Americans than in the groups with greater skin pigmentation. Of the 5 groups studied in detail, the one with the lowest estimated protein intake had significantly higher serum total protein values than did the others. Women in the villages of La Gartarita and Parita had serum total protein values considerably above those reported for the United States or the Canal Zone, despite a lower protein intake. However, the women from these villages average much lower in serum carotene values. These and other biochemical data are discussed in relation to the diet histories and the clinical states represented.

Vitamin C deficiency in the ringtail monkey

JAMES H. SHAW. *School of Dental Medicine, Harvard Univ., Boston, Mass.* The ringtail or brown capuchin monkey (*Cebus fatuellus*) is of interest in dental investigations because of its relatively small adult size and its tractability. Investigations of the ringtail monkey's need for various nutrients have been conducted in this laboratory to determine how similar its nutritional requirements were to those of man and the rhesus monkey. In a study of whether vitamin C was required in the diet, 10 young adult ringtails were offered a purified diet which was believed to be adequate in all known nutritional essentials but deficient in ascorbic acid. These monkeys maintained their original body weight, normal appearance and activity reasonably well for periods of 12 to 20 weeks when the classical manifestations of a chronic state of scurvy began to appear. The deficiency was characterized by rapidly increasing debility, moderate decreases in body weight, extreme tenderness of the joints and extensive hemorrhages over large areas of the head, arms and legs. Oral lesions were particularly severe and rapidly progressing, with widespread hyperemia, hypertrophy and necrosis of the gums accompanied by extensive destruction of alveolar bone and sloughing of the teeth. The injection or oral administration of crystalline ascorbic acid soon after gross manifestations of scurvy appeared resulted in extremely slow but complete recovery. Administration of ascorbic acid at later stages was ineffective. Comparable ringtail monkeys offered the same diet supplemented with adequate ascorbic acid were maintained in normal health throughout the experimental period.

Nutritional evaluation of the iso-oleic acids Elaidic, petroselinic and petroselinelaidic acids. HENRY SHERMAN (by invitation), LAURA M. CAMPBELL (by invitation), WILLY LANGE (by invitation) and ROBERT S. HARRIS. *Nutritional Biochemistry Lab., Massachusetts Inst. of Technology, Cambridge, Mass.* Male weanling rats were fed diets consisting of 20% casein (Labco) 61.5% corn starch, 14% fat, 4% salts and liberal quantities of 14 vitamins. The fat in each of four diets varied as follows: olive oil randomized with an equal quantity of a) trielaidin (Δ^9_{10} trans), b) tripetroselinin ($\Delta^{6,7}$ cis), c) tripetroselinelaidin ($\Delta^{6,7}$ trans) or d) pure olive oil. Olive oil was used because it contains 80-85% Δ^9_{10} cis oleic acid. Distilled water and diets were supplied *ad libitum* for 42 days and rats were weighed biweekly. Before sacrifice data were taken for body surface calculations. The fatty acids extracted from the various groups of pooled carcasses were analyzed for iodine value, neutralization value and arachidonic acid content. The results indicate that rats on a) grew less rapidly, had smaller body surface and the carcass fat contained less arachidonic acid than rats fed d). Rats fed b) grew better than those fed c) and their carcass fat contained more arachidonic acid. Rats fed c) grew less and de-

posited less arachidonic acid than those fed *d*. Rats fed *b* grew as well as those fed *d*, but their carcass fat contained less arachidonic acid. *Cis* isomers of $\Delta^{6,7}$ and Δ^{11} oleic acids appear to be more nutritious than their respective *trans* isomers, and the $\Delta^{6,7}$ *trans* isomer more nutritious than the Δ^{10} *trans* isomer.

Influence of dietary protein and fat on the toxicities of trinitrotoluene (TNT) and 2,4-dinitrotoluene (DNT) for the rat MAURICE E. SHILS and LEONARD J. GOLDWATER (introduced by C. G. KING) *Division of Industrial Hygiene, School of Public Health, Columbia Univ., New York, N. Y.* Conflicting reports have been published on the effect of diet on the closely related compounds TNT and DNT. A study was made of the comparative effects of protein, fat and carbohydrate on both TNT and DNT toxicity by feeding to rats diets which contained low and high levels of each of these nutrients. The intake of each toxic compound was kept equal for each group. The growth-inhibiting effect of DNT (fed initially at 300 mg % level in low fat diets and 600 mg % level in high fat diets) was less pronounced when the fat content of the diet was increased from 6.0% of the dietary calories to 60.0%. The beneficial effect of fat was noted on both the high and low protein diets. Variations in fat intake had little effect on the growth of rats on low protein diets receiving TNT (fed initially at 150 mg % level in low fat diets and 300 mg % level in high fat diets). The DNT and TNT-treated rats and their controls on the diets containing protein equivalent to 25% of the calories all grew at better rates than similarly treated animals on diets containing protein at half this level. The treated groups grew less than the controls but since the absolute increases in weight of each of these three groups in response to the higher protein intake was of the same order of magnitude, it appears that protein has little or no specific effect in overcoming the growth inhibition of the toxic compounds. However, at the higher protein intake there were no deaths in the DNT-poisoned rats as compared to a high mortality on the low protein diets.

Radioactive phosphorus in the study of caries-resistant and susceptible albino rats RAY L. SHIRLEY (by invitation) and CARL A. HOPPERS *Kedzie Chemical Laboratory, Michigan State College, East Lansing, Mich.* In 1931-32 Hoppers et al. demonstrated that dental caries could be developed in rats by feeding diets containing coarsely ground corn or rice. Subsequently, a genetic study was undertaken with Hunt in which two distinct strains of albino rats were developed that vary markedly in their susceptibility to dental caries. The present study was undertaken to compare some chemical constituents of the teeth of these developed strains. The caries-resistant and susceptible rats have been demonstrated in this investigation not to differ significantly in the following respects: a) weight of

teeth, b) % ash, c) % phosphorus on the basis of dry weight, and in the ash, d) rates of deposition and removal of radioactive phosphorus in the teeth when the isotope was injected into the peritoneal cavity, e) occurrence of radioactive phosphorus in the teeth of offspring of females that were injected intraperitoneally with the isotope during pregnancy, f) the *in vitro* adsorption of the isotope by the teeth from aqueous solution. The data obtained indicates that the differences in susceptibility to dental caries of the rats used in this study are not due to differences in the phosphorus metabolism of the teeth.

Determination of vitamin-D activity in the rat by means of radioactive phosphorus R. H. SNYDER (by invitation), HAROLD J. EISNER (by invitation) and HARRY STEENBOCK *Dept. of Biochemistry, Univ. of Wisconsin, Madison, Wis.* In the course of an investigation of the mechanism of vitamin-D activity it was found that the response of the rachitic rat to the administration of radiophosphorus could be directly quantitated to small amounts of vitamin D. The vitamin was administered orally in a single dose a short time before the tracer was given intraperitoneally. An external 'count' of the forepaw of the anesthetized rat was chosen as the simplest technique of measurement. A relatively simple apparatus was designed for placing a rat in a reproducible position under a mica end-window G. M. tube for counting. Though a difference in the external count due to D developed almost immediately after administration of the P^{32} it was found that the best time to take the counts was from 8 to 10 days later. The counts of groups with different doses were compared with a control group which received no vitamin D, or with a group receiving a known dose, and/or with previously established reference curves. Although no attempt was made to develop the method exhaustively, the collected data indicate quite definitely that it is possible to determine vitamin D accurately over a range of from one-half to 40 units with groups of 10 animals each. Good results were obtained using a preparatory period as short as 14 days on ration 2965.

An unidentified dietary factor concerned in human growth SELMA E. SNYDERMAN (by invitation), ROSA LEE NEMIR (by invitation) and L. EMMETT HOLT, JR. *Dept. of Pediatrics, New York Univ. and the Children's Medical Service, Bellevue Hospital, New York City.* In the course of studies designed to measure the requirements for B vitamins we have had occasion to feed a number of infants on purified diets. The diets were constructed from vitamin-free casein, crisco and a special de-vitaminized dextrimaltose; they provided 15% of the calories as protein, 35% as fat and 50% as carbohydrate. This was supplemented by a mineral mixture, a fish oil concentrate to supply fat-soluble vitamins and a mixture of water-soluble vitamins containing ascorbic acid, thiamine, riboflavin, nico-

tinamide, pyridoxine, pantothenic acid, inositol, choline and p-amino benzoic acid. Biotin and pteroyl glutamic acid were added in more recent studies. Only one component of the vitamin mixture, that which was being studied, was varied at a time. Barring a few intercurrent infections, the infants remained in good health and gained weight normally. It was observed, however, that if the experimental diet was continued for more than 5 to 6 months a cessation of weight gain would occur regularly, although the infants still gave every appearance of health. Attempts to supplement the experimental diet with amino acids or by increasing the quantities of B vitamins failed to restore weight gain. The addition of Brewer's yeast caused resumption of weight gain in from 5 to 23 days, but the weight gain was in some instances subnormal. Liver preparations have given inconclusive results. Return to natural food caused resumption of normal weight gain at once.

Influence of dietary proteins on the urinary excretion of amino acids by human subjects. BETTY F STEELE (by invitation), MAY S REYNOLDS (by invitation) and C A BAUMANN *Dept of Biochemistry and Home Economics, College of Agriculture, Univ of Wisconsin, Madison, Wis*. Two separate controlled diet studies were made. In the first study 3 adults ingested diets containing 25, 50 and 100 gm of protein/day for periods of 6 days. The principal sources of protein in this study were eggs and cottage cheese. In the second experiment 4 subjects consumed diets containing 25, 100 and 200 gm of protein/day for 6 days. The main sources of protein were ground beef, white bread and milk. Twenty-four hour samples of urine were collected and analyzed microbiologically for 18 amino acids. Both 'free' and 'total' amino acids were determined in the urines, and the amino acid contents of the diets ingested were also determined. Large amounts of 'free' histidine and cystine were present in the urine samples. Glutamic acid, glycine, histidine, aspartic acid, serine, proline, threonine, tryptophan and methionine were present in fairly large quantities in samples of hydrolyzed urine. Increasing the protein intake four fold caused roughly a 2-fold increase in the excretion of alpha amino nitrogen. Of those amino acids present in large amounts, histidine and threonine excretion appeared to bear a positive relationship to intake. Glutamic acid, aspartic acid, tryptophan and methionine excretion seemed to be independent of the amount of the amino acid ingested. Many of the other amino acids were present in urine in only low concentrations.

Ascorbic acid metabolism of older adolescents. CLARA A STORVICK, BESSIE L DAVEY (by invitation), RUTH M NITCHALS (by invitation), RUTH E COFFEY (by invitation) and MARGARET L FINCKE *Nutrition Research Laboratory, Agr Exp Sta,*

Oregon State College, Corvallis, Ore. In 1946-47, 4 levels of ascorbic acid intake were studied during periods of 7 days each, and in 1947-48, 3 levels were studied during periods of 10 days each. The subjects, 8 girls and 8 boys, were 16 to 19 year-old Freshmen. During the first year, 1946-47, the subjects received the following for periods of 7 days each: 1) their usual diets, 2) a daily supplement of 200 mg of crystalline ascorbic acid in addition to the ascorbic acid in the food, 3) the total daily ascorbic acid intake as recommended by the National Research Council, and 4) 10 mg of ascorbic acid less than they received during the third period. During the second year, 1947-48, the subjects received the following for periods of 10 days each: 1) a daily supplement of 200 mg of crystalline ascorbic acid in addition to the ascorbic acid in the food, 2) the total daily ascorbic acid intake as recommended by the National Research Council, and 3) 10 mg less than they received during the second period. The recommended allowance of the National Research Council did not maintain mean plasma values as high as their respective means during the saturation period when they received 200 mg supplements of crystalline ascorbic acid. A decrease in ascorbic acid intake to 10 mg less than the recommended allowance resulted in a statistically significant decrease in plasma ascorbic acid concentration for only 2 of the 8 girls and for 1 of the 7 boys (values for one boy were not included because of illness).

Role of pyridoxine in economy of food utilization. BARNETT SURE and LESLIE EASTERLING (by invitation) *Univ of Arkansas, Fayetteville, Ark*. Twenty four male and 24 female albino rats were depleted of pyridoxine. In 26 to 59 days 15 pairs developed dermatitis which were used for this study which was conducted in pairs. In each pair the positive control, which received 25 μ g pyridoxine daily, was allowed the same amount of food consumed by its litter mate, which received no pyridoxine. The average results were as follows,—P representing the pathological or pyridoxine-deficient animals, and C the litter mate controls which received pyridoxine. Food consumption P, 325 gm, C, 317 gm, gains in body weight P, 37.5 gm, C, 77.3 gm, gains in weight/100 gm food intake, P, 11.4 gm, C, 25.2 gm, changes in chemical composition of body gains: fat P, -0.24 gm, C, +8.1 gm, protein P, 9.3 gm, C, 17.5 gm, ash P, 2.2 gm, C, 3.4 gm.

Synthesis of amino acids in the rumen. W E THOMAS (by invitation), J K LOOSLI, FENT H FERRIS (by invitation), HAROLD H WILLIAMS and L A MAYNARD *Depts of Animal Husbandry and Biochemistry and Nutrition, Cornell Univ, Ithaca, N Y*. Growing goats and sheep were fed purified diets that contained, at a 10% protein-equivalent level: 1) casein, 2) casein hydrolysate plus trypto-

phan, and 3) urea as the only source of nitrogen. Normal growth was obtained with diets 1) and 2) and $\frac{1}{2}$ normal with diet 3). Biological values, determined from nitrogen balance studies, were higher for diets 1) and 2) than for 3). The content of 10 amino acids (those that have been shown to be essential for rats) of the feeds and of rumen and excreta samples was determined microbiologically. The results showed that the essential amino acid content of the rumen material was similar for the urea and casein diets. Although traces of amino acids were found in the purified diet where urea was given as the sole source of nitrogen, the amounts in the rumen per gram of total nitrogen were 9 to 20 times that ingested. Furthermore the daily loss of each of the essential amino acids in the excreta more than accounted for the traces found in the purified diet. These data together with the surprising growth of the animals indicated a remarkable synthesis of amino acids from urea nitrogen by rumen organisms.

Nutrition of *L. Bifidus*, predominant intestinal organism of the breast fed infant. R. M. TOMARELLI (by invitation), R. F. NORRIS (by invitation), PAUL GYORGY, *Univ. of Pennsylvania Hospital, Philadelphia*, J. B. HASSINEN (by invitation) and F. W. BERNHART (by invitation), *Wyeth, Inc., Mason, Mich.* In the isolation of strains of *bifidus* anaerobically from breast fed infant stools it was observed that better growth was had if milk were added to the conventional liver infusion medium. Skimming did not decrease activity. An ether soluble fraction was isolated whose activity could be replaced by Tween 80, methyl oleate, oleic, linoleic or vaccenic acid. The exact nature of the factor in milk is unknown at present. The various strains of *bifidus* could be grown on a synthetic medium containing acetate buffer if milk or oleate were added. Human milk contains approximately 4 times as much activity as cow's milk. With citrate as the buffer, milk, but not oleate, yielded growth. Citrate proved toxic to the organism, the toxicity being neutralized by the addition of Ca of the milk. The strains varied in their sensitivity to citrate toxicity. Citrate toxicity is the result of the binding of essential minerals. Mn appears to be the only mineral affected, since removal of Mn but not of Fe nor Mg from the acetate medium decreased growth. The utilization of glucose and especially of lactose was influenced by the autoclaving of the carbohydrate with the medium. Unautoclaved lactose was not utilized even after 64 hour incubation. When sterile milk was used as a source of unautoclaved lactose, growth was had in 40 hours indicating the presence of a factor in milk that rendered lactose available. Several strains of *bifidus* were isolated that required unknown growth factors in enzymatic digest of casein.

Relation of factor in a methanol extract of liver and pteroylglutamic acid in mink. S. B. TOVE (by invitation) and C. A. ELVEHJEM, *Dept. of Biochemistry, College of Agriculture, Univ. of Wisconsin, Madison, Wis.* The previously reported (*Proc. Soc. Exp. Biol. & Med.* 62: 169, 1946) pteroylglutamic acid (PGA) deficiency syndrome in mink can be relieved by the administration of a methanol extract of fresh liver (fed at a level of 1 ml/100 gm ration) which contains only 2 γ PGA/ml. If this level of extract is added to the ration from the start, symptoms of a PGA deficiency fail to occur. The addition of 0.3% of a crude antagonist (7-methyl PGA) to a diet containing 0.1 mg PGA/100 gm ration resulted in rapid loss of body weight and hemoglobin. When the inhibitor is added to a ration containing the extract, no deficiency syndromes were seen. Microbiological assay of the PGA content of the blood, urine and feces of mink receiving 0.0, 0.025, 0.1 mg PGA/100 gm ration, and the extract in addition to the low and high levels of PGA indicate that the extract caused an increase in the PGA greater than can be accounted for by the PGA in the extract. Mink receiving the basal diet or this diet supplemented with PGA fail to respond when given vitamin B₁₂ preparations or commercial liver extracts used in pernicious anemia therapy, but when the methanol extract is given a response is obtained. It is thus apparent that the methanol extract factor, which is different from vitamin B₁₂, has a sparing action on pteroylglutamic acid.

Tyrosine excretion in rheumatoid arthritis and normals. E. B. WALLRAFF (by invitation), C. A. STEPHENS (by invitation), A. BORDEN (by invitation), P. HOLBROOK (by invitation), D. HILL (by invitation), L. J. KENT (by invitation) and A. R. KEMMERER, *Dept. of Nutrition, Univ. of Arizona, and Southwestern Clinic and Research Institute, Tucson, Ariz.* Increased tyrosine excretion in pregnancy has been reported (Lawrie, *Biochemical J.* 41: 41, 1947). The relief of the rheumatoid arthritic syndrome during pregnancy has occasioned investigations to determine the possible mechanism of relief. Using a slight modification of the microbiological procedure for urines of Woodson et al (*J. Biol. Chem.* 172: 613, 1948) and the medium of Henderson and Snell (*J. Biol. Chem.* 172: 15, 1948), tyrosine was assayed in 24-hr urine specimens from rheumatoid arthritis and normals as well as pregnant rheumatoid arthritis and pregnant normals. It appears that tyrosine which is bound so as to be microbiologically unavailable without hydrolysis is higher in rheumatoid arthritic urine than in normal urine. Diet analysis for caloric and protein intake indicates no significant differences between the two groups. The difference may in part be due to differences in assimilation of protein, or may possibly be due to metabolic abnormality. Studies on excretion of other amino acids are in progress.

THE AMERICAN ASSOCIATION OF IMMUNOLOGISTS

Thirty-third Annual Meeting

DETROIT, MICHIGAN, April 18-22, 1949

(For possible corrections in any of the following abstracts see the June issue)

Studies on the enzymatic hydrolysis of the capsular polysaccharide of *Klebsiella pneumoniae* Type B EDGAR E BAKER (by invitation) and WALTHER F GOEBEL *Laboratories of The Rockefeller Institute for Medical Research, New York City* It has been observed that the capsular polysaccharide of *Kl pneumoniae* Type B (FrB), when administered to embryonated eggs is capable of inhibiting the multiplication of mumps virus In order to obtain degradation products of FrB which could be used for studying the mechanism of this inhibitory action, a search has been made for a specific enzyme A motile, gram-negative, spore-forming bacillus has been isolated from soil, which elaborates an enzyme capable of hydrolyzing the polysaccharide Although the microorganism will grow in a medium containing di- or trisaccharides, but not monosaccharides, it can elaborate the enzyme only when FrB is present Ammonium or nitrate ions, casamino acids or peptone may serve as sources of nitrogen Growth factors are not required The enzyme may be obtained from culture filtrates of the microorganism grown in the presence of 0.1% FrB It may be prepared more economically, however, by first culturing the bacilli in a medium containing sucrose and then resuspending the organism in a small volume of medium containing FrB The enzyme specifically hydrolyzes solutions of FrB The former can be determined quantitatively by observing the rate of change of viscosity at 30° and at pH 5.0 The drop in viscosity of the polysaccharide is followed by a loss of serologic activity If the hydrolysis proceeds to completion, the liberation of reducing sugars occurs It is not yet known whether the depolymerization of the carbohydrate and its hydrolysis are caused by a single enzyme

Comparison of methods of determining differences in virulence for mice of strains of *Salmonella typhosa* H C BATSON, MAURICE LANDY and MARTHA BROWN (introduced by MARION C MORRIS) *Dept of Biologic Products, Army Medical Dept Research and Graduate School, Army Medical Center, Washington, D C* Methods employed for determining the virulence for mice of strains of *S typhosa* have been of two main types The first, as utilized almost exclusively by British

workers, is based on the intraperitoneal injection of graded doses of the organisms suspended in saline The second, as employed by most American workers during the past decade, is essentially similar but incorporates the use of 5% hog gastric mucin as a suspending medium A third method which has shown some promise is based on intracerebral injection without the aid of an adjuvant A direct comparison of the efficacy of these methods in detecting differences in virulence of strains of *S typhosa* previously has not been made Such a comparison was the objective of this investigation Strains of *S typhosa* grown under different but defined nutritional conditions were tested for their virulence for mice by the 3 methods described Differences in virulence of the strains could not be determined satisfactorily by the intracerebral method Fatalities resulting from different strains of organisms were comparable but in each case were only poorly related to the size of challenge dose employed Differences between the strains were more distinct when the organisms were administered intraperitoneally as saline suspensions Furthermore, mortality was more clearly dependent upon the size of the challenge dose With the use of mucin as an adjuvant, differences in virulence of strains of organisms were amplified markedly and became readily apparent The effect of dosage on mortality was greatly accentuated It appears that assessment of the virulence of strains is dependent upon the method of testing employed The method incorporating the use of mucin as an adjuvant was the most sensitive in detecting differences in virulence, the intracerebral method was the least sensitive

Further study of toxins and antigens of *Shigella dysenteriae* DANIEL A BOROFF and BEATRICE P MACRI (by invitation) *Camp Detrick, Frederick, Md, Dept of Bacteriology, and George Washington Univ, Washington, D C* In previous studies of serological and immunological properties of toxins and antigens of *Shigella dysenteriae* (Boroff, D A, *Federation Proc* 7: 301, 1948) a suggestion was offered that there may be only 1 dominant antigen in *S dysenteriae* In these studies the data obtained in active protection experiments indicate that it is possible to immunize rabbits with either smooth

or rough whole organisms of *Shigella dysenteriae* or with their respective toxins and thus induce active protection against lethal doses of these substances. Not only whole organisms or solutions of whole organisms afford protection against each other but both chemically and physically purified toxins protected the animals and induced the formation of identical and reciprocally absorbable antibodies. This phenomenon of cross protection is not in accord with the concept that 2 toxins and 2 distinct antigens exist in *S. dysenteriae*. It is, however, explainable by the presence of 1 dominant antigen in the organism. Furthermore, the protection afforded rabbits against the whole organisms of the smooth variant by immunization with toxic lysates of the rough variant lends additional support to the latter hypothesis.

Immunologic relations and comparative invasiveness of strains of poliomyelitis from recent epidemics. GORDON C. BROWN (by invitation), THOMAS FRANCIS, JR. and JOHN D. AINSLIE (by invitation). *Dept. of Epidemiology, School of Public Health, Univ. of Michigan, Ann Arbor, Mich.* The immunologic relationship of strains of poliomyelitis virus was determined by means of virus neutralization tests performed in monkeys. The strains of virus had been obtained from the following epidemics: Cleveland, 1941, Texas, 1943, Buffalo, 1944, Rockford, Illinois, 1945, Tennessee, 1945, Ann Arbor, 1945, and Minnesota, 1946. Several dilutions of each virus were mixed with serum obtained from monkeys convalescent to infection with the various strains under study. Complete reciprocal testing between strains has not been possible but the results clearly demonstrate that all the viruses, with the exception of the Tennessee strain, are closely related immunologically. While studying each of these strains of virus certain characteristic differences in invasiveness were noted. After compiling data from all monkeys infected with each strain it was observed that variation occurred in the percentage showing fever, the height and duration of fever, the percentage, type and degree of paralysis and other clinical signs. Certain of these variations were so characteristic as to partially identify the strain of virus.

Evidence for the controlling influence of protease-inhibitors in allergic phenomena. KENNETH L. BURDON. *Dept. of Bacteriology and Immunology, Baylor Univ. College of Medicine, Houston, Texas.* Traditional theories about allergy, based entirely upon the amount and distribution of antibodies, and upon the supposedly crucial importance of the site of antigen-antibody union in the body, have never been adequate to explain satisfactorily the diverse manifestations of hypersensitivity in man and in different animal species. Yet some universal, underlying mechanism must operate. There is

increasing evidence that such a mechanism is to be found in the system of natural proteases, their inhibitors and activators, present in body fluids. According to this concept, allergic reactions are initiated by the sudden activation of natural proteases, following antigen-antibody combination, and are prevented by the action of protease-inhibitors. New support for this view has been obtained by use on an extended scale of a greatly improved procedure permitting the strictly quantitative titration of the antitrypsin in samples of blood serum and other fluids by a rapid, routine test. Results with several hundred specimens from allergic persons and normal controls, and from sensitized guinea pigs, have shown a sudden drop in antitrypsin in the first seconds of anaphylactic shock, a rise following sub-lethal reactions, and a consistent association of an especially high trypsin-inhibitor titer with the 'desensitized' state, whether this condition was induced by specific or by non-specific means. It was demonstrated that the 'anergy' to tuberculin exhibited at times by some tuberculous men and animals is always accompanied by a markedly increased antitryptic power of the blood.

Prophylactic immunity to experimental enteric cholera. WILLIAM BURROWS and LAWRENCE WARE (by invitation). *Dept. of Bacteriology and Parasitology, Univ. of Chicago, Chicago, Ill.* It was shown earlier that experimental enteric cholera in the guinea pig produced by overwhelming doses (viz., 20 mg.) of the vibrios is sharply modified by prior active immunization, in the immunized animal the percentage vibrios of the total fecal flora is reduced from 50-70% to 1-10% and the period of excretion shortened from 2-3 weeks to 5-7 days. If the inoculum is reduced both of these effects are observed in the normal animal but the ratio of total vibrios excreted to those inoculated becomes very large, many thousand fold, indicating that a true infection is produced. With progressive reduction a minimal dose infecting 50% of the animals (ID_{50}) may be calculated by the usual methods, in this case by inverse probability. The ID_{50} dose for the normal 300-400 gm. guinea pig has been found to be 0.08 mg. (32 million vibrios). In animals immunized with 0 vaccine and infected 4 days after the last of 3 inoculations, the ID_{50} is raised to 1.13 mg., a 14.1 fold increase over the normal. Two weeks later the immunity has fallen off so that the ID_{50} is 0.170 mg., an 8.7 fold increase over the normal. Following passive oral immunization the ID_{50} is immediately raised to 0.36 mg., a 4.05 fold increase, and rises to 0.51 mg., or a 6.4 fold increase 2 weeks later, the latter coinciding with maximum excretion of absorbed antibody. It is concluded that the presence of antibody in the feces is associated with prophylactic immunity to experimental enteric cholera in the guinea pig.

Purification of antibodies by specific methods

DAN H CAMPBELL and LEONARD LERMAN (by invitation) *Gates and Crellin Laby of Chemistry, California Inst of Technology, Pasadena, Calif* Methods have been developed for the efficient removal and purification of antibodies from serums. These methods are based on the removal of antibody with soluble or insoluble antigens and subsequent dissociation with simple specific hapten or dilute acid or both. Recent experiments with adsorption columns or suspensions of R-azo-coagulated egg white and R-azo-phenol-formaldehyde resins indicate that such systems usually remove more antibody than is realized by use of soluble precipitating antigens. Studies have been made chiefly with rabbit antibodies against ovalbumin and p azophenyl arsonate, and include quantitative studies on specific adsorption.

Interference with induction of the anaphylactic state by prior feeding of a hapten-like allergenic chemical MERRILL W CHASE *Rockefeller Inst for Medical Research, New York City* The feeding of allergenic chemicals, such as 2,4-dinitrochlorobenzene and picryl chloride to guinea pigs that have not previously encountered the respective substance, conditions the animals so that the outcome of subsequent attempts to induce hypersensitivity is profoundly modified. The conditioned animals fail to respond, or they respond abortively, to various sensitizing procedures effective in normal animals. This inhibitory effect is observed not only when attempts are made to develop a specific dermal sensitivity of the 'delayed type' but also when anaphylactic sensitization is undertaken. Guinea pigs that have been fed picryl chloride, for example, and have then been treated with an 'artificial antigen' made by coupling the proteins of guinea pig serum with the picryl radical as the serologically determinant grouping show no or scarcely any anaphylactic effects upon challenge with other conjugates having the same determinant grouping. There exists, accordingly, a specific mechanism that can modify the outcome of sensitizing procedures and that results in a certain level of tolerance; the influence of this mechanism is probably encountered also in natural exposures of human beings to sensitizing agents.

Comparative response and persistence of immunity in mice vaccinated intra-abdominally or by gavage with *Shigella sonnei* MERLIN L COOPER, HELEN M KELLER and AGNES M HART (introduced by ALBERT B SABIN) *Children's Hospital Research Foundation and Dept of Pediatrics, College of Medicine, Univ of Cincinnati, Cincinnati, Ohio* One group of mice was vaccinated intra-abdominally with one injection of 100 million killed *Shigella sonnei* as broth vaccine. A control group was given intra-abdominally 1 injection of an equal volume of uninoculated broth medium.

Another group of mice was given by gavage, daily for 15 days, one billion killed *Sh sonnei* as broth vaccine. A control group was given by gavage, daily for 15 days, an equal volume of uninoculated broth medium. One week, 6 weeks and 12 weeks following completion of vaccination, mice from the 2 vaccinated groups and the 2 control groups were challenged intra-abdominally with the homologous *Sh sonnei* suspended in 3% sterile mucin. The mice vaccinated intra-abdominally withstood after 1 week more than 24,000,000 LD₅₀ doses of culture, after 6 weeks 5,000,000 LD₅₀ doses and after 12 weeks 1,700,000 LD₅₀ doses. The mice vaccinated by gavage withstood after 1 week 263,000 LD₅₀ doses, after 6 weeks 5,600 LD₅₀ doses and after 12 weeks 85 LD₅₀ doses. The range of LD₅₀ doses of culture withstood by the groups of control mice was from less than 10 to 30. Data will also be presented regarding the passive mouse protective powers and agglutinative titers of sera obtained from each group of mice 1, 6 and 12 weeks following completion of vaccination.

Antisheep agglutinins in infectious mononucleosis, further studies I DAVIDSOHN and CHIYO KASHIWAGI (by invitation) *Mount Sinai Medical Research Foundation and Chicago Medical School, Chicago, Ill* In over 200 patients with infectious mononucleosis antisheep agglutinins were studied in the serum. Earlier observations on the ability of certain antigens to remove the agglutinins were confirmed: beef erythrocytes completely absorbed the agglutinins present in infectious mononucleosis, whereas guinea pig kidney was unable to do so. In more than $\frac{1}{2}$ of the tests, the guinea pig antigen removed from 50-75% of the originally present agglutinins, less than $\frac{1}{10}$ of the tests showed a maximum absorption of 87.5%, and in no instance of infectious mononucleosis was complete removal of the agglutinins observed. According to recent reports bovine albumin as diluent raises the titer of antisheep agglutinins in infectious mononucleosis. This problem was reinvestigated by studying the effect of several diluents on the titers of the agglutinins. Under standard conditions, bovine albumin and human plasma used instead of saline as diluent lowered the titers in both the absorbed and unabsorbed serums, or left them unchanged. Investigation of the effect of time and temperature of incubation showed that prolonged incubation at ice-box temperature increased the titers, and hence the sensitivity of the test. This effect was independent of the diluent. Studies are also reported on the preparation of the guinea pig kidney and beef red cell antigens used in the differential test.

Polysaccharides isolated from tissues of normal, immune, and immunologically paralyzed mice LLOYD D FELTON, BENJAMIN PRESCOTT (by invitation), GLADYS KAUFFMANN (by invita-

tion) and BARBARA OTTINGER (by invitation) *Laby of Infectious Diseases, Microbiological Inst., National Inst of Health, Bethesda, Md*. A preliminary observation has been reported that, when mice were inoculated with a large dose (0.5 mg) of pneumococcus antigenic polysaccharide, their immunological system was 'paralyzed' so that they failed to respond to a subsequent immunizing dose. From the tissues of such mice it was possible to separate a soluble antigen which was antigenic in both precipitin and active immunity tests. In continuing this study, a comparison has been made of the polysaccharide which has been obtained from the tissues of a) normal mice of C₃H strain, b) mice immunized with 0.002 mg of antigenic polysaccharide of each type, I, II, and III respectively, and c) mice immunologically paralyzed with type I, II, and III. The tissues studied included blood, heart, lung, liver, kidney, spleen, lymph, thymus, stomach, bone marrow, muscle, and skin. Like tissues from 10 mice of each of these groups were pooled, ground, and a polysaccharide obtained by methods employed for isolating antigenic polysaccharide from pneumococci. The product, a dry white powder, was soluble in 7.5% trichloroacetic acid and at neutral pH, and insoluble in alcohol. In all alike, tests for glycogen and protein were negative. The polysaccharide so obtained from tissues of normal mice failed to demonstrate antigenic activity. The immunized mice gave low yields of polysaccharide which showed a comparatively low titer immunity in 9 of the 12 tissues of the type I mice, in 10 of the type II tissues, and in 6 of the type III tissues. The immunologically paralyzed mice, on the other hand, yielded greater amounts of polysaccharide. Furthermore, the immunizing titer was appreciably higher in the polysaccharides from the tissues of these 'paralyzed' mice.

Procaine penicillin and sulfonamide antagonism. H. FISHBACK (by invitation), H. WELCH, E. Q. KING (by invitation), J. LEVINE (by invitation), C. W. PRICE and W. A. RANDALL *Federal Security Agency, Food and Drug Administration, Washington, D. C.* Procaine has long been known as an antagonist of the sulfonamides. This antagonism may result through direct action of the procaine as such or through conversion of the procaine to p-aminobenzoic acid. The accepted ratio of procaine-antisulfonamide action is much lower than the PABA-antisulfonamide action. The introduction of procaine-penicillin as a chemotherapeutic agent raised the question as to whether sufficient procaine or procaine derivatives would be formed in the body to act antagonistically toward sulfonamides during combined therapy. Accordingly, 1,500,000 units of procaine penicillin for aqueous injection was administered to 37 individuals and blood was drawn for examination 3 hours

after the injection. The penicillin levels were determined and the serum examined for procaine, p-aminobenzoic acid and an acylated derivative of p-aminobenzoic acid. The concentration of penicillin varied from 0.5-8.0 u/ml, averaging 2.5 u/ml. The blood concentration of procaine was approximately 0.1 µg/ml in 68% of the cases. None could be detected in the remainder. A level of 0.1 µg/ml, for PABA was found in only 18% of the cases. However, previous reports indicate that this concentration of PABA is sufficient to antagonize the therapeutic action of sulfanilamide but insufficient to interfere significantly with the therapeutic action of sulfathiazole or sulfadiazine. An acylated derivative of PABA was found in each of the 37 individuals in quantities ranging from 0.2-1.0 µg/ml. *In vivo* experiments are now under way to determine the actual antagonism when experimental infections are treated with combined therapy.

Neutralization technique in *Tsutsugamushi* disease (scrub typhus) and the antigenic differentiation of Rickettsial strains. JOHN P. FOX (introduced by P. K. OLITSKY) *International Health Board, Rockefeller Foundation, New York City*. Neutralization of *R. orientalis* by homologous antiserum was most effectively demonstrated when mice were inoculated by the intraperitoneal route with mixtures of undiluted antiserum and serial dilutions of infective material. Satisfactory results could not be obtained by employing a constant infective dose and serial dilutions of antiserum nor by using the subcutaneous or intracerebral routes of inoculation. Furthermore, neutralization was independent of complement. Evidence was obtained to suggest that neutralization depends principally upon a union of antigen and antibody *in vitro*, however, passive immunity may best explain the zone phenomenon often observed. The satisfactory expression of the neutralizing capacity of an antiserum was rendered difficult by the above mentioned zone phenomenon and by the otherwise frequently irregular pattern of mouse survival observed in neutralization tests. In spite of this difficulty, it was possible on the basis of a large series of cross-neutralization tests to distinguish 4 clearly differentiated antigenic types and a possible 5th type among the 8 strains of *R. orientalis* included in the study. The strains and the grouping observed were as follows: 1) *Karp* (from New Guinea), 2) *Queensland* (from Australia), *Raub* (from Malaya), *Seerangayee* (from Malaya), 3) *Calcutta* (from India), *Imphal* (from India), 4) *Gilliam* (from Assam-Burma border), 5) *Pescadores* (from Pescadores Islands). These results augment evidence previously reported by others as to the antigenic heterogeneity of strains of *R. orientalis*, a fact of importance epidemiologically.

and from the standpoint of developing vaccines of proper antigenic composition

Streptococcal anti-hyaluronidase in rheumatic fever SUSANNA HARRIS (by invitation) and T N HARRIS *Children's Hospital of Philadelphia, Dept of Pediatrics, School of Medicine, Univ of Pennsylvania, Philadelphia, Penna* The occurrence of antibodies to streptococcal hyaluronidase, as measured by the mucin-clot-prevention test, was studied in groups of convalescents from streptococcal infection, in patients with acute rheumatic fever and in the normal population. In preliminary studies the optimal relations of hyaluronidase, the substrate (hyaluronic acid) and neutralizing antibody were determined, the potency of the enzyme as measured by mucin-clot-prevention (*in vitro*) was compared with spreading activity (*in vivo*) in the rabbit's skin, and the serologic specificity of neutralizing antibodies was established by comparative studies against hyaluronidase of testicular, clostridial and pneumococcal origin. It was found that antibodies to streptococcal hyaluronidase occurred with increasing frequency in the normal population from infancy up to the adult age group. Following streptococcal infection there was an increase in the titer of antibodies to streptococcal hyaluronidase and in acute rheumatic fever the titer was found to be still higher. In a comparative study of the antibody response to 4 streptococcal antigens, hyaluronidase, hemolysin, and 2 somatic fractions, the cytoplasmic particles and supernate proteins, it was found that the mean titers to all of these antigens were elevated in both rheumatic and streptococcal infection. The mean titer was somewhat higher in rheumatic than in streptococcal infection, in the case of 3 of these antibodies. In the case of the 4th, anti-hyaluronidase, this difference was considerably greater. The anti-hyaluronidase titer showed better correlation with changes in the activity of the rheumatic infection than did the other tests. There was, however, no striking correlation between this titer and the severity of the illness. The possible implications of these data, both diagnostic and etiologic, are discussed.

Histochemical evidence for the synthesis of protein by lymphocytes following parenteral injection of antigen T N HARRIS and SUSANNA HARRIS (by invitation) *Children's Hospital of Philadelphia, Dept of Pediatrics, School of Medicine, Univ of Pennsylvania, Philadelphia, Penna* Recent developments in histochemistry have indicated that cells which are actively forming new protein are characterized by large amounts of ribonucleic acid in their cytoplasm. Since there is considerable immunologic evidence of the production of antibody by the popliteal lymph node of the rabbit following the injection of antigens in the foot pad, and since a tissue in which antibody is being

formed could be expected to show evidences of protein synthesis, it seemed feasible to attempt to identify the cells involved by histochemical methods. A study was therefore undertaken of the localization and concentration of ribonucleic acid in the cells of the popliteal lymph node in correlation with the production of antibody by that node. Antigens were injected into the foot pads of rabbits, and at various intervals thereafter the draining lymph nodes were examined histologically and chemically. Diffuse hyperplasia was found in the cortex of the lymph node, involving transitional forms between reticulum cells and lymphocytes, as well as young (large) lymphocytes. Large numbers of these cells showed pyronine staining granules (ribonucleic acid) in the cytoplasm, which were abolished by previous incubation of the sections with protease-free ribonuclease or with hot trichloroacetic acid solution. Pyronine-staining nucleoli and crescents of cytoplasm were also seen in these cells. Chemical analysis of the nodes showed an increase in ribonucleoprotein but not in desoxyribonucleoprotein. These changes reached a maximum intensity just before the time of maximal antibody content of the node.

Dissociation of antigen-antibody complexes and their bond energy FELIX HAUROWITZ and LALE ETILI (by invitation) *Dept of Chemistry, Indiana Univ, Bloomington, Indiana, and Dept of Medical Chemistry, Istanbul, Turkey* Experiments 4.5 ml rabbit immune serum against anthranil-azo-beef serum globulin, mixed with 10 mg antigen, kept at 37° for 30 minutes and at -12°C for 24 hours, gave 27.8 mg precipitate, containing 3.0 mg antigen. No precipitate resulted with 150 mg antigen. When the precipitate produced by 10 mg antigen was kept at 37° for 30 minutes with 140 mg antigen, a considerable part was dissolved. The weight of the undissolved precipitates (in bracket antigen) was 9.5 (3.7), 8.8 (3.3) and 12.1 (4.6) mg in 3 experiments. The precipitates were isolated and analyzed as described previously (J Immunol 43:331, 1942). —Results 6 of the 8 antibody molecules bound per antigen molecule in the original precipitate are split off by the antigen excess. No antigen is split off. —It is assumed that the irreversibly bound antibody molecules are attached to antigen molecules by the whole area of the determinant site. If an area of 50 Å² is assumed for the bis-azophenylcarboxylic group and 100 Å² for the species-specific group of the globulin, a total bonding area of 150 Å² results, corresponding to 14 water molecules per layer. The bond energy between antigen and antibody must be higher than that of the water displaced from this area. If it is assumed that only 1 layer of water molecules is displaced, a bond energy of ~70 kcal 1 antigen-antibody bond or ~0.47 kcal 1 Å² results. The loose linkage of those antibody molecules

which are split off by the antigen excess is attributed to steric hindrance by the firmly bound antibody molecules and/or to imperfect complementarity of the specific sites. Both factors cause increase of the distance between bonding groups. If this distance increases from 3 to 4, 5 or 6 Å, the bond energy will decrease from ~ 0.47 to approximately 0.25, 0.15 and 0.10 kcal/Å² respectively.

Indirect complement-fixation test for psittacosis-lymphogranuloma venereum group antibodies in chicken antisera. M. R. HILLEMANN and, R. J. HELMOLD (introduced by ANNABEL WALTER), *Dept. of Virus and Rickettsial Diseases, Army Medical Dept. Research and Graduate School, Army Medical Center, Washington, D. C.* It is well established that antisera prepared in certain mammals and birds are incapable of fixing complement in the presence of homologous antigen even though antibody can be demonstrated in them by other techniques. Such sera may contain blocking antibodies which, in the presence of homologous antigen, prevent fixation of complement by ordinary antibodies that are capable of binding complement. Sera from chickens immunized against viruses of the psittacosis-lymphogranuloma venereum group do not fix complement in the usual type of test. Such sera have now been shown to possess blocking antibodies which interfere with the binding of complement by mammalian antibodies in the presence of homologous antigen. The technique of the indirect complement-fixation test has been used to determine whether under these conditions chicken antisera provide the broad group reaction displayed by mammalian antisera in complement-fixation tests with this group of agents, or whether they follow the highly strain specific reaction found when chicken antisera are used in neutralization tests. It would appear that when the indirect complement-fixation technique is employed, the chicken sera approach the broad type of group reaction characteristic of mammalian sera in direct fixation tests with this group of viruses.

Tissue reaction to foreign particulate matter altered by presence of adsorbed antigen. HOWARD C. HOPPS and ALFRED M. SHIDELER (by invitation), *Dept. of Pathology, School of Medicine, Univ. of Oklahoma, Oklahoma City, Okla.* Rabbits were given intradermal injections of finely particulate aluminum hydroxide, activated carbon, magnesium silicate (talc) and silicon dioxide (flint). Tissue reactions were studied at 7, 14, 28 and 56 days. A second series of intradermal injections was made, similar to the first, with the exception that horse serum was absorbed upon the particulate matter prior to its administration. Tissue reactions in this group of lesions were compared with those of the former group with special attention to the character of inflammatory exudate, ratio between macro-

phages and fibroblasts, occurrence of focal necrosis and cellular degenerative changes.

Effect of previous experience with homologous and heterologous types of poliomyelitis virus upon the alimentary carriage of virus by the chimpanzee. HOWARD A. HOWE (by invitation), DAVID BODIAN (by invitation) and ISABEL M. MORGAN, *Poliomyelitis Research Center, Dept. of Epidemiology, The Johns Hopkins Univ., Baltimore, Md.* Eighty oral inoculations have been carried out in chimpanzees with 4 strains of poliomyelitis virus representing 2 major immunologic types, the Brunhilde, Kotter and Frederick strains comprising 1 type, and the Lansing strain the other. The first experience with virus was provided by oral inoculation in the majority of the animals but toward the end of the experiment 14 animals were vaccinated with active Lansing virus given intramuscularly. Evidence of response to the immunization was obtained by testing for virus in stools or for rises in serum antibody titer. The control group consisted of 27 animals of which all responded positively, 2 with paralysis. Challenge was carried out at 1 month or later following first virus contact by the oral administration of titrated pools of rhesus monkey cords. In many instances 2 or 3 homotypic viruses were given to the same animal. Animals which became paralyzed or carried virus in the stools after the first post inoculation week were considered to have shown no evidence of immunity. No animal was considered negative unless no evidence of activity was found in at least 4 stool specimens collected during the 2-4th weeks and tested in 2 monkeys each by intranasal inoculation. The results were as follows. Of 9 animals receiving homologous challenge, 1 subsequently produced virus in the stools. This result differs in no essential respect from the results of 22 homotypic challenges in which 1 animal had virus in the stools on the second week. Twenty-two animals were immunized with Lansing virus either by mouth (8) or by intramuscular vaccination (14). Subsequent oral challenge was carried out with the heterotypic Brunhilde strain, following which 3 animals became paralyzed while 13 showed virus in the stools. Although the tests are not quite complete the infection rate appears to be 15/22 or 68%.

Universal serologic reaction with lipid antigen in tuberculosis. REUBEN L. KAHN, *Serology Lab., Univ. Hospital, Ann Arbor, Mich.* It was previously shown that it is possible to demonstrate positive reactions with the serums of normal human beings by special precipitation techniques with tissue extract antigens (Kahn, Kolmer, cardiopipin). A standardized precipitation technique based on different NaCl concentrations, serum dilutions and incubations was then developed with Kahn antigen, known as universal serologic technique. With this technique normal human beings

(giving negative Kahn reactions for syphilis) give precipitation reactions of characteristic serologic patterns. It was observed that, in Kahn-negative patients with acute tuberculosis, precipitation in the universal reaction is increased above the normal level and, as the patients gradually improve, precipitation is correspondingly decreased. This finding indicates that the universal serologic technique might prove helpful as an indicator of tuberculous activity. No increase in precipitation above the normal has been noted in far advanced and terminal cases of tuberculosis.

Development of the specific antibody for a distinctive constituent of Brown-Pearce carcinoma cells. BERNARD KALFAYAN (by invitation) and JOHN G. KIDD, *Dept. of Pathology, New York Hospital, Cornell Medical Center, New York City*. Certain rabbits implanted with Brown-Pearce tumor cells develop an antibody that reacts specifically with a distinctive constituent of them, as previous work has shown (J. Exper. Med. 71: 335, 351, 1940). In ordinary market-bought hybrid rabbits the specific Brown-Pearce antibody was frequently masked by the presence of induced tissue antibodies, which react with extracts of a variety of normal and neoplastic rabbit tissues (J. Exper. Med. 82: 21, 1945), though about half of the inbred 'blue-cross' rabbits implanted with Brown-Pearce tumor cells developed the specific antibody in high titer, usually without the concomitant development of the induced tissue antibodies (J. Exper. Med. 82: 41, 1945). In recent experiments the specific Brown-Pearce antibody appeared in the blood of every one of 17 Havana and 23 Chocolate-Dutch (Havana x Dutch hybrids) rabbits implanted with the tumor cells, often reaching titers of 1:512 or higher. The induced tissue antibodies, by contrast, were present in titers of 1:8 or less in a few specimens but were entirely absent from most of them. Normal rabbits of both breeds provided sera that were devoid of the specific Brown-Pearce antibody and of the induced tissue antibodies.

Quantitative measurement of antibody to a whole bacterial antigen. MARIAN KOSHLAND (introduced by WILLIAM BURROWS), *Dept. of Bacteriology and Parasitology, Univ. of Chicago, Chicago, Ill.* A quantitative method for the measurement of the antibody response to a whole bacterial antigen, the cholera vibrio, has been developed. The method depends upon the colorimetric determination of specific complement fixation using the 50% hemolytic unit. The excess complement procedure, proposed by Heidelberger and his co-workers, was employed in this study, and was adapted to the requirements of a whole bacterial antigen. The results obtained using a whole bacterial antigen have been compared from a theoretical and practical point of view with those involving viral or bacterial extract antigens. The method has been used to

determine the antibody levels produced in the serum and the feces of guinea pigs, either actively immunized with the cholera vibrio or passively immunized with anti-cholera rabbit serum.

Equilibrium studies on the reaction of antibody with hapten. LEONARD LERMAN (introduced by DAN H. CAMPBELL), *Gates and Crellin Lab. of Chemistry, California Inst. of Technology, Pasadena, Calif.* Quantitative studies have been made on the combination of antibody with a simple monohaptenic substance. Antibody was specifically purified from rabbit antiserum homologous to the p-azophenylarsonic acid hapten by precipitation with a simple trihaptenic antigen, followed by dissociation of the washed precipitate with a monohaptenic substance. A cellophane bag containing the purified antibody solution was immersed in a buffered solution of normal rabbit gamma-globulin (at the same protein concentration) together with a dialysable monohaptenic dye. After continuous agitation at constant temperature for about 24 hours the dye concentrations in the 2 solutions were measured colorimetrically to obtain the equilibrium composition in terms of bound and unbound hapten. From measurements at varying ratios of hapten to antibody the free energy of combination, the maximum binding capacity, and related quantities have been determined. Under various conditions the free energy change is of the order of -7.5 to -8.0 kcal per M of hapten bound.

Some properties of purified diphtheria toxoid. LEO LEVINE and LOUISE WYMAN (introduced by GEOFFREY EDSALL), *Antitoxin and Vaccine Lab., Massachusetts Dept. of Public Health, Boston, Mass.* Crude toxoid, obtained as the detoxified filtrate of diphtheria bacillus culture grown on Mueller's semi-synthetic medium, modified in this laboratory, has been purified by a simple 2-stage salt fractionation, and has been evaluated with respect to purity, antigenicity, and stability. Preparations have been obtained assaying 2100 Lf/mg of protein nitrogen. Preliminary laboratory studies have indicated that stability of the toxoid protein is impaired by addition of glycine to the diluent in the usual quantities, whereas gelatine appears to increase stability. Injections of 11 Lf have protected guinea pigs against the standard challenge dose of 10 M.L.D. Potency tests with varying amounts of antigen indicate that the antigenicity per Lf unit increases as the purity is increased. A linear relationship has been observed between the logarithm of the flocculation time (K_f) and that of the dilution (or of the Lf) at the equivalence point. These observations support the evidence of previous workers that a relationship may be established between antigenic efficiency and flocculation time. This product is now on clinical trial; the practical significance of the findings presented will be discussed.

Allergenic fraction of ragweed pollen prepared by electrophoresis-convection (Nielsen-Kirkwood cell) MARY HEWITT LOVELESS and ROBERT BEST (by invitation) *New York Hospital and the Dept of Medicine, Cornell Univ Medical College, New York City* The principle of electrophoresis-convection has been applied to the problem of fractionating ragweed extract, with the eventual aim of obtaining a single allergen from pollen. The Nielsen-Kirkwood apparatus affords a gentle means of separation and larger yields of fraction than are available from the Tiselius cell used by Abramson. Preliminary results with products obtained from one or more runs in the Nielsen-Kirkwood apparatus reveal that the electrophoretically immobile material (called 'top' fraction) is simplified over the original extract. This is evidenced by a) the almost complete removal of color from this fraction, b) reduction in precipitable nitrogen as well as in carbohydrates, c) a decrease in reagin-binding activity roughly related to its loss of precipitable nitrogen, d) immunological crosstests which showed removal of some antigenic constituents. Despite the purification of 'top' fraction, it uniformly elicited the characteristic immediate responses in allergic skin and conjunctiva, as well as producing the typical Prausnitz-Kustner reaction with pollen-allergic sera. Occasional sera were encountered which contained reagins for only those antigens which remained in the 'top' fraction. Patients who were given a course of therapeutic injections with 'top' fraction produced 'protective,' or thermostable, antibodies in their blood streams and showed increased tolerance toward the fraction when tested intracutaneously and by conjunctival test. Furthermore, a significant proportion of them proved to be resistant clinically when exposed to natural pollination. This clinical immunity tended to be selective since some individuals responded much better to the fraction than they had to whole extract in prior years, while for others the reverse was true.

New observations on an autoagglutinin H H LUBINSKI and D MENDEL (by invitation) *Pathological Lab and Dept of Medicine, Jewish General Hospital, Montreal, Canada* The serum of a patient suffering from hemolytic anaemia and belonging to Blood Group A contained an autoagglutinin which had the following characteristics. When serum dilutions and red cell suspensions were made with normal saline, clumping of red cells was observed at room temperature, but not at 37°C, clumps dissolved if warmed to incubator temperature. When, instead of saline, 30% beef albumin solution was used, agglutination also occurred at incubator temperature. Using human serum or plasma, clumping occurred only at room temperature. The autoantibodies could be adsorbed on human cells of Group A or O and transferred into normal saline with the

technique described by Landsteiner and Miller, even when the whole process was perfected in an incubator room at 37°C. These purified agglutinin solutions reacted with human red cells, suspended in saline, at room temperature, but not at 37°C; red cells suspended in albumin were clumped at 37°C as well. The agglutinin solution, furthermore, agglutinated and hemolyzed rabbit red cells suspended in saline at both temperatures.

Relation of complement to thermolabile hyaluronidase inhibitor of serum STANLEY MARCUS and JOHN K FULTON (by invitation) *Rackham Arthritis Research Unit and Dept of Medicine, Univ of Michigan, Ann Arbor, Mich* A modification of a biological technique (streptococcal decapsulation) for the quantitative determination of hyaluronidase using testicular or streptococcal enzyme has been used. By this method and turbidimetric assay also, it was found that sera heated at 56°C for 20 minutes lost their enzyme inhibiting capacity. Activity of the enzyme inhibitor decreased during refrigeration. These findings suggested an analogy to complement (C') function. Loss of inhibition following heating was replaced by addition of lyophilized guinea pig C'. While fresh guinea pig serum contained inhibitor, reconstituted lyophilized serum did not. It was concluded that inhibition depends upon a thermostable component lost upon lyophilization and a thermolabile component surviving this process. Pooled guinea pig serum was fractionated to yield C'3 and C'4 deficient C'. Both C'3 and C'4 deficient fractions lacked enzyme inhibitory capacity. Although heated guinea pig serum (C'3, C'4) plus ammonia or zymine-treated serum did not show inhibitory capacity, heated serum plus ammonia and zymine-treated fractions of C' had fully restored inhibitory ability. It has been assumed, therefore, that serum inhibitor of hyaluronidase depends upon the presence of the 4 characterized C' components plus still another thermostable component. Although it is demonstrable by turbidimetric procedure that heated serum does not inhibit enzyme action, preliminary data indicate that C' will not reactivate the thermolabile inhibitor measured by this technique. This is believed to be further evidence that different procedures may measure different stages in the hydrolysis of hyaluronic acid. There was no fall in inhibitor concentration of guinea pig serum following anaphylaxis, whereas C' concentration was decreased. C' concentrations of human sera could not be correlated with inhibitor titers. The implications of these findings will be discussed.

Effects of ghotoxin and other sulfur-containing compounds on tumor cells *in vitro* JOHN W MASON (by invitation) and JOHN G KIDD *Dept of Pathology, New York Hospital, Cornell Medical Center, New York City* Ghotoxin, held in brief contact with tumor cells *in vitro*, inhibits their subsequent

proliferation upon implantation in susceptible hosts, as previous work has shown (Science 105 511, 1947) Two other compounds having unusual sulfur linkages (4-acetamido-5,5-dimethyl-1,2-dithiolane-3-one and 4-methyl-5-methylimino-1,2-dithiazolidone-3—synthesized and made available by Professor John R. Johnson) have likewise proved highly effective against lymphosarcoma cells in mice, inhibiting their growth after 1 hour's contact *in vitro* in concentrations of 1–5 $\mu\text{g}/\text{cc}$, the effective level of gliotoxin in concurrent tests being 1 $\mu\text{g}/\text{cc}$ or slightly less Two additional compounds of similar sort (4-benzamido-5,5-dimethyl-1,2-dithiolane-3-one and 4-methyl-5-methylimino-3-thio-1,2-dithiazolidone-3), were somewhat less soluble, but were also inhibitory in low concentrations Dethiogliotoxin had no effect on tumor cells in concentrations of 800 $\mu\text{g}/\text{cc}$ Simple monothiol compounds (cysteine, glutathione, and monothioglycerol) had no inhibitory effect on the lymphosarcoma cells in concentrations up to 800 $\mu\text{g}/\text{cc}$, while two dithiols, BAL and dithiobiuret, were inhibitory at 100–200 $\mu\text{g}/\text{cc}$ When mixtures containing low concentrations of gliotoxin and high concentrations of the mono- and dithiol compounds were allowed to interact for a few minutes and then tested against tumor cells, the inhibitory effect of the gliotoxin was diminished or abolished This effect of gliotoxin was not modified, however, when very large amounts of cysteine, glutathione, monothioglycerol and BAL were brought into contact with tumor cells that had previously been exposed for 1 hour to gliotoxin in a concentration of 10 $\mu\text{g}/\text{ml}$

Immunogenic difference between two related strains of poliomyelitis virus JOSEPH L. MELNICK
Section of Preventive Medicine, Yale Univ School of Medicine, New Haven, Conn By means of vaccination and neutralization tests the 2 strains of poliomyelitis virus—Lansing and Y-SK—are immunologically related The Lansing strain, isolated in the monkey from the CNS of a fatal case in Lansing, Mich, in 1937, was successfully established by Armstrong in cotton rats and mice When used in the present experiments, the strain had been through 260 serial passages in mice and still retained its pathogenicity for monkeys The Y-SK strain, isolated by Trask and Paul from the stools of an abortive case in New Haven, Conn, in 1937, was subsequently found to produce in mice, cotton rats, and hamsters a myelitic disease The virus transferable in these rodents was shown to be immunologically the same as the parent simian strain At the time it was used for these experiments, this strain had been passed through 20 transfers in monkeys and 15 in cotton rats and mice It too remained pathogenic for primates Previous work had established that single or multiple feedings of the Y-SK virus to cynomolgus monkeys usually result in the production of antibodies either by the first day of

paralysis or by the 4th week in the asymptomatic animals When the Lansing virus was fed repeatedly to a group of cynomolgus monkeys, none of them responded either by apparent disease or by the development of neutralizing antibodies When these same monkeys were then fed Y-SK virus, they again remained in apparent good health, but they were now found to have developed neutralizing antibodies Subsequent challenge by the intranasal route indicated an appreciable degree of resistance among the group Thus in contrast to the Lansing strain of poliomyelitis virus, the homotypic Y-SK strain is capable of engendering antibodies when it is administered orally to cynomolgus monkeys and such monkeys may have an increased resistance to virus instilled intranasally

Resistance to endotoxins of enteric bacilli in patients convalescent from typhoid and paratyphoid fever HERBERT R. MORGAN and FRANKLIN A. NEVA (introduced by THOMAS FRANCIS, JR.)
Dept of Epidemiology, School of Public Health, Univ of Michigan, Ann Arbor, Mich Patients convalescent from enteric fevers due to infection with *Salmonella typhosa* or *S. paratyphi* were shown to be more resistant than normal individuals to the pyrogenic and general systemic effects of the toxic, somatic antigens (endotoxins) of *S. typhosa* or *Shigella dysenteriae* following their intravenous administration The significance of these findings in regard to the clinical course of the disease and the process of recovery will be discussed

Precipitin tests for the diagnosis of Chagas' disease, with special reference to the specificity of polysaccharides A. PACKCHIANIAN and L. TURCK (by invitation) Dept of Bacteriology and Lab of Microbiology, Univ of Texas, School of Medicine, Galveston, Texas *Trypanosoma cruzi* antigens for diagnosing Chagas' disease by the precipitin test were prepared from washed, packed *Tr. cruzi* grown *in vitro* The cytolysis of the trypanosomes was accomplished by various means, and the active principle for the precipitin test was extracted by several methods The first antigen, a crude aqueous extract, was found to be specific and gave positive precipitin reactions with both *Tr. cruzi* antiserum and sera from known human and animal cases of Chagas' disease Inasmuch as the precipitin titer of this aqueous antigen was low, further studies were conducted to isolate from the cellular substance of *Tr. cruzi* the active component, which proved to be the polysaccharide complex Several well known immunochemical methods of isolating polysaccharides from microorganisms, such as Avery's, Felton's, Fuller's and Sevag's methods, were employed in the preparation of *Tr. cruzi* 'polysaccharide antigens' The specificity and potency of these antigens were determined and compared These antigens gave much higher precipitin titers than the crude aqueous extract Quantitative studies of serological

cross reactions between the *Tr cruzi* antigens and several antisera and serum samples from other trypanosomiasis, leishmaniasis and bacterial infections were made. Likewise, polysaccharides isolated from several species of trypanosomes, leishmania and bacteria were tested with *Tr cruzi* and homologous antisera. The relative merits of the *Tr cruzi* antigens for the precipitin test in the diagnosis of Chagas' disease have been evaluated.

Amino acids, analogues and the propagation of Theiler's GD VII virus in mouse brain tissue culture HAROLD E. PEARSON and RICHARD J. WINZLER (by invitation) *Depts of Bacteriology and Biochemistry, Univ South Calif School of Medicine and the Laby Div, Los Angeles County Hospital, Los Angeles, Calif*. The effects of various amino acids and certain analogues on the propagation of the GD VII strain of Theiler's mouse encephalomyelitis virus in cultures of minced, one day mouse brain were studied. Tissue suspended in Simm's solution at pH 8-9 and contained in 50 ml Erlenmeyer flasks was incubated for 2-3 days at 35°C. The titer of virus attained in cultures as tested by intracerebral injection of mice was reduced slightly by the presences of 1 mg/ml L-lysine monohydrochloride but not by L-arginine monohydrochloride, L-cystine, L-cysteine hydrochloride, glycine, L-histidine monohydrochloride, L-leucine, L-proline, DL-alanine or DL-phenylalanine. The titer was markedly reduced by the presence of 3-5 mg/ml DL-ethionine, beta-2-furyl-DL-alanine or beta-2-thienyl-DL-alanine, the addition of DL-phenylalanine in the same concentration did not reverse the actions of the last 2 compounds. Glutathione 5 mg/ml but not 1 mg/ml also reduced the titer of virus in cultures.

Effect of lithium periodate on crystalline bovine serum albumin GERTRUDE E. PERLMANN (by invitation) and WALTHER F. GOEBEL *Labys of The Rockefeller Inst for Medical Research, New York City*. When certain biologically active proteins are subjected to the action of dilute lithium periodate at physiological values of pH, their activities are rapidly altered and finally destroyed. In order to gain an insight into the nature of the chemical changes which occur, a study has been made of the action of 0.03 M lithium periodate on crystalline bovine plasma albumin. It has been found that after contact with the reagent the ultraviolet absorption spectrum as well as the electrophoretic behavior of the protein has been radically altered. In addition, the solubility of the protein in salts has been changed, as has its solubility in the acid range of pH values. At a pH of approximately 3.5 the protein is entirely insoluble, but dissolves as the solution becomes more acid. The cystine, cysteine and tyrosine content of the protein has been greatly lowered, and the tryptophane appears to be completely destroyed following treatment with 0.03 M

lithium periodate at room temperature over a period of 72 hours. These chemical and physico-chemical changes are accompanied by a complete loss in the ability of the oxidized protein to incite antibodies in experimental animals, yet the changes are not so profound as to cause loss in precipitability of the oxidized albumin in an antiserum prepared against the native protein.

'Nonspecific' complement-fixing activity of cloudy avian sera CHRISTINE E. RICE *Div of Animal Pathology, Science Service, Dominion Dept of Agriculture, Animal Diseases Research Inst, Hull, Quebec, Canada*. Whereas inactivated chicken and turkey sera do not ordinarily fix complement with homologous bacterial or viral antigens, an atypical type of complement-fixing activity has been observed with higher dilutions of sera collected from birds during periods of active egg-production. Since fixation of complement was recorded with normal as well as immune sera and was noted with various unrelated antigens, it appeared to be 'nonspecific' in nature. The fact that fixation was most pronounced with cloudy sera suggested that serum lipids may have played some rôle in the reaction. The results of chemical analyses seemed to support this supposition. The possible relationship of such activities to certain 'nonspecific' reactions encountered in the serologic diagnosis of human infection will be discussed.

Relationship between catalase activity and virulence in *Pasteurella pestis* MORRIS ROCKENMACHER (introduced by A. P. KRUEGER) *Office of Naval Research Task V, Dept of Bacteriology and U S Naval Medical Research Unit No 1, Univ of California, Berkeley, Calif*. The catalase activity of virulent and avirulent strains of *Pasteurella pestis* was measured by an adaptation of the procedure of Huddleson (*Univ of Michigan Technical Bulletin* 182 January 1942). Optimal conditions for enzyme activity in these organisms, as shown by a study of the kinetics of the reaction, were used. Catalase activity was expressed as ml of 0.1 N hydrogen peroxide decomposed in 60 minutes by a standardized suspension of organisms. A minimum of 2 separate measurements was made for each strain. Enzyme activity appeared to follow the curve for a mono-molecular reaction. The catalase activity of virulent strains was greater than that of avirulent strains. In the 14 virulent strains studied, enzyme activity ranged from 12.9 to 19.9 ml, with a mean value of 16.7 ± 0.4 . For 11 avirulent strains, values of 2.1 to 8.6 ml were found, with a mean value of 5.1 ± 0.5 . The difference between the mean values of the virulent and avirulent organisms was significant. Virulence titrations were simultaneously performed by the subcutaneous inoculation of the suspension of organisms used for catalase testing into 7- to 12-week old mice. The resultant LD₅₀ values ranged from 6 to

5000 virulent organisms. Avirulent strains caused no deaths when 20,000 organisms were injected subcutaneously.

Intradermal antibody-antigen and antigen-antibody reactions in persons having poliomyelitis, contacts and non-contacts in relation to poliomyelitis EDWARD C. ROSENOW *Bacteriological Research, Longview Hospital, Cincinnati, Ohio*. The solutions of thermal antibody and of antigen injected intradermally consisted of the bacteria-free supernatants of saline suspensions of streptococci isolated in studies of poliomyelitis. The former after autoclaving suspensions containing twenty billion streptococci/ml for 96 hours and adding an equal volume of saline containing 0.4% phenol, the latter after heating suspensions containing ten billion streptococci/ml at 70°C for one hour and adding 0.2% phenol. Three hundredths ml of each and of control solutions were injected into the skin of the anterior aspect of the forearm of 432 persons having poliomyelitis, of 434 contacts and 2193 non-contacts. Reactions of 5 sq cm or more to 'poliomyelitis' streptococcal thermal antibody indicating specific antigen and a corresponding streptococcal infection occurred in all persons having poliomyelitis, in nearly all contacts and non-contacts during September and in almost no one in spring and winter remote from poliomyelitis. Reactions indicating antigen were greatest, alike in males and females, and reactions indicating antibody were least at the onset of poliomyelitis. Antigen diminished and antibody increased during recovery far more rapidly in persons having mild attacks than in persons severely paralyzed and antibody titers were uniformly higher in females than in males corresponding to the lower incidence of and mortality from poliomyelitis in females. 'Poliomyelitic' streptococcal antibody titers in September were strikingly greater in persons recovering, in persons that had recovered from mild poliomyelitis and in well persons that had previously been exposed to epidemic poliomyelitis than in corresponding persons not previously exposed.

Antigenic relationship of dengue and yellow fever viruses with those of west-Nile and Japanese B encephalitis ALBERT B. SABIN *The Children's Hospital Research Foundation, Univ of Cincinnati College of Medicine, Cincinnati, Ohio*. Rhesus monkeys inoculated intracerebrally with human serum containing various immunological types of dengue virus (Hawai, New Guinea 'B,' 'C' or 'D') developed complement-fixing antibodies not only for the Hawai dengue virus (benzene extracted 20% mouse brain antigen) in titers of 1:64 to 1:128 but also for the Japanese B and West Nile viruses in titers of 1:16 to 1:64 and to a lesser degree for the virus of yellow fever, but not for the St. Louis, Western equine or Rift Valley fever viruses. The serum of human volunteers residing in the U. S. A.

who recovered from infection with the Hawai type of dengue virus by mosquito bites or inoculation of human serum, also had C-F antibodies for the Japanese B, West Nile and yellow fever viruses, but not for the St. Louis, Western equine, or Rift Valley fever viruses. Rhesus monkeys inoculated with yellow fever virus (French neurotropic or Asiatic viscerotropic strains or both) which developed C-F antibodies for the yellow fever virus in titers of 1:64 to 1:256 also regularly developed C-F antibodies for the Japanese B and West Nile viruses in titers of 1:4 to 1:32 and occasionally also for the Hawai dengue virus, but not for the St. Louis, Western equine or Rift Valley fever viruses. A Japanese B antiserum prepared in mice with a homologous C-F titer of 1:256, had a titer of 1:128 with West Nile, 1:32 with yellow fever, 1:4 with Hawai dengue, 1:2 with St. Louis encephalitis virus, and yielded negative results with similar antigens prepared from the Western equine and Rift Valley fever viruses. The common antigen (or antigenic groups) possessed by the dengue, yellow fever, Japanese B encephalitis and West Nile viruses is present in low concentration and can be demonstrated only in the most potent preparations, although it is not necessarily proportional to the number of homologous antigenic units. Thus, while a Japanese B antigen with 128 homologous units had only 4 units when tested with a dengue antiserum, the West Nile antigen with 16 homologous units was as active as the Japanese B antigen in its reaction with the antisera for the related viruses.

Differences in antigenic capacity among influenza virus strains JONAS E. SALK, ANGELA M. LAURENT (by invitation) and RACHEL C. MCGINNIS (by invitation) *Virus Research Lab., Dept of Bacteriology, Univ of Pittsburgh School of Medicine, Pittsburgh, Penna.* In the course of studies carried out in 1947-48 employing influenza virus vaccines containing the FM1 strain (Type A-prime), it was observed that the antibody response in man to the FM1 component of the vaccine was noticeably less than was the response to the other two components, PR8 (Type A) and Lee (Type B). For this reason studies were undertaken to investigate the hypothesis that strains of influenza virus differ in their antigenic capacity. Because of the importance of this question, in relation to continuing field studies of vaccination, a study was made, in man as well as in experimental animals, of the antigenic capacity of selected strains. The studies in man were carried out by inoculating groups of individuals with univalent vaccines containing comparable amounts of virus hemagglutinin. Determinations were then made of the titer, in the pre- and two-week post-vaccination sera, of hemagglutination-inhibition antibody, measured with homologous and heterologous antigens. Similarly, groups of mice were inoculated intraperitoneally

with the univalent vaccines, diluted serially, to determine antigenic extinction titer. The latter is an index of the highest dilution of vaccine that is capable of inducing, in the mouse, the formation of neutralizing antibody measured *in ovo*. Both in man and in the mouse, marked differences were found in the effectiveness of different strains in calling forth antibody. It was of further interest that different lines of the same strain differed in this respect. The implication is evident of the significance of these findings in relation to the problem of selecting strains of virus to be included in vaccines for use in man.

Loss of hemolytic complement and of granulocytes following reinjection of an antigen into the rabbit. A. B. STAVITSKY (by invitation), R. STAVITSKY (by invitation) and E. E. ECKER, *Inst of Pathology, Western Reserve Univ., Cleveland, Ohio*. The decrease of complement observed in anaphylaxis, serum sickness and certain infectious diseases has been attributed to its fixation by an antigen-antibody complex *in vivo*. To determine whether such fixation occurs, the following experiments were performed. Various antigens were injected into rabbits and their serum complement estimated immediately before and after the intravenous reinjection of each antigen. Thirty and 60 minutes after the reinjection of the antigens, such as ovalbumin, etc., a great reduction of hemolytic complement activity was noted. This reduction occurred both in the presence and absence of anaphylaxis. Since it did not occur in the absence of extracellular antibody, it is most likely that complement was bound by an extra-cellular antigen-antibody complex *in vivo*. A similar mechanism may be assumed to mediate the loss of complement in allergic and infectious diseases. The 'Complement Reduction Reaction' may prove to be useful for the detection of extracellular antigens and antibodies. It is highly specific and sensitive, apparently unaffected by excess antigen or antibody, and may require relatively little antigen for its production, but is not as yet quantitative. A granulocytopenia generally accompanies the drop in complement. This response appears to be related to anaphylactic and anaphylactoid reactions as well as to an *in vivo* antigen-antibody combination. This response may be employed for the early detection of the anaphylactic type of hypersensitivity to a given antigen. The significance of the loss of antibody, complement and granulocytes during the early part of the 'negative phase' in immunization deserves further clarification.

Antigen-antibody reaction of intact leukocytes. 1. Plasma cell, 2. Variable specificity of maturing cells. BERNHARD STEINBERG and RUTH A. MARTIN (by invitation), *Toledo Hospital Inst of Medical Research, Toledo, Ohio*. We indicated previously (*Proc Soc Exp Biol & Med* 56: 50-52, 1944, J

Immun 51: 421-426, 1945, 52: 71-75, 1946, 53: 137-141, 1946) that various types of mature and immature INTACT leukocytes possess specific antigenic substances and that each cell type can be demonstrated by agglutination. Normal and leukemic leukocytes were found to be antigenically similar, whereas cells from lymphosarcoma were antigenically dissimilar from those of lymphatic leukemia. These findings suggest an immunochemical difference between normal and leukemic cells on one hand and malignant cells on the other. In the present study, the antigenic similarity of the plasma cell in relation to other leukocytes was investigated. In addition, leukocytes of various stages of immaturity were tested for antigenic specificity. Antisera were developed for granulocytes, lymphocytes, monocytes and plasmocytes of mature and of several phases of immaturity. Agglutinations of intact leukocytes indicated individual variations but with a group specificity for all immature forms of a given type of cell. Plasmocytes were found to be antigenically dissimilar from granulocytes, lymphocytes and monocytes.

Metabolism of Brown-Pearce rabbit carcinoma cells in normal and immune serum. W. H. SUMMERSON (by invitation) and JOHN G. KIDD, *Depts of Biochemistry and Pathology, Cornell Univ Medical College, New York City*. The metabolism of viable Brown-Pearce rabbit carcinoma cells was studied in the presence of normal rabbit serum and of rabbit serum that contained high titers of the antibody that reacts with a distinctive constituent of the Brown-Pearce cell. For the immune sera, the relation between the number of cells and the volume and titer of serum used was such that an excess of the specific antibody was present. Measurements were made of oxygen consumption, R.Q., aerobic and anaerobic glycolysis, glucose utilization, and lactic acid production, over a 3 to 4-hour period, under physiological conditions of temperature and pH. No significant effect of the immune sera on these metabolic characteristics of the Brown-Pearce cell was evident, even though control bioassays demonstrated that incubation of the cells with immune sera under conditions similar to those used in the metabolism studies rendered the cells incapable of giving rise to new tumors when implanted in susceptible host rabbits.

Antigenicity of staphylocoagulase. MORRIS TAGER and HARRIET B. HALES (by invitation), *Dept of Bacteriology, Yale Univ School of Medicine, New Haven, Conn.* Although the antigenicity of coagulase has been a matter of controversy, interest in this problem has been reopened by studies indicating that many human sera inhibit coagulase activity, that similarly most plasmas show varying degrees of resistance, and that changes in inhibitory properties of sera may follow staphylococcal infection. Using standardized and

concentrated coagulase purified 300-fold (activity to nitrogen ratios) and showing 2 mobile components on electrophoresis, rabbits were inoculated with a) coagulase alone, b) coagulase plus Wood 46 alpha lysin as adjuvant, and c) the lysin only. Five of 6 test rabbits developed an increase in serum neutralization, increased plasma resistance to coagulase action, complement fixing bodies, and agglutination of coagulase-coated collodion particles. The 3 controls and 1 test animal failed to respond. The antigenicity of the coagulase, and the specificity of the responses observed, is further supported by such considerations as the high degree of purity of the injected coagulase, the consistently better response of the animals treated with the adjuvant toxin as well as the coagulase, by the sharp anamnestic reaction following a single booster dose, and by the specific removal of neutralizing bodies by adsorption on coagulase-coated collodion particles. Although the findings warrant the conclusion that antibodies were produced to coagulase in 5 or 6 rabbits, there are data indicating that coagulase activity may be blocked by other mechanisms as well.

X-irradiation on antibody decline WILLIAM H. TALIAFERRO and LUCY G. TALIAFERRO (by invitation) *Dept of Bacteriology and Parasitology, Univ of Chicago, Chicago, Ill.* Changes in hemolysin titer have been followed by photometric methods in 3 series of rabbits after receiving per kg: 1) 2×10^7 sheep red cells in one injection, 2) 2×10^8 cells in one injection, and 3) 17×10^9 cells in 12 injections. After the antibodies began to decline, half of each series was irradiated twice (1 or 2 weeks apart) with 400 r hard X-rays (0.5 mm copper and 1 mm aluminum filters). In no animals was there a significant rise in hemolysin titer after irradiation. At this level of irradiation there is marked destruction of lymphocytes but the macrophages are highly phagocytic and show no evidence of injury. In view of the accumulated evidence indicating that lymphocytes contain large amounts of antibody, these negative results raise questions as to 1) the relative importance of the macrophages and lymphocytes in producing and storing antibodies at this stage of immunization, and 2) the possibility that the particular method used to destroy lymphocytes may lead to the destruction of antibody.

Tuberculostatic activity of the blood and urine of animals given gliotoxin RALPH TOMPSETT (by invitation), WALSH McDERMOTT (by invitation), and JOHN G. KIDD *Depts of Medicine and Pathology, The New York Hospital, Cornell Medical Center, New York City*. Two samples of purified gliotoxin, generously provided by Professor Johnson, have regularly inhibited the growth of virulent tubercle bacilli of human origin in concentrations of 0.01-0.04 $\mu\text{g/ml}$ in various liquid media. These

samples were likewise effective against mouse lymphosarcoma cells *in vitro* in concentrations of 1.0 $\mu\text{g/ml}$ or slightly less, as indicated in the preceding abstract. The purified gliotoxin was much less active against a number of other bacterial species, the inhibitory concentrations ranging from 250 $\mu\text{g/ml}$ for *Ps. aeruginosa* to 8.0 and 4.0 $\mu\text{g/ml}$ for *Str. viridans* and *Pneumococcus* respectively. Concentrations within this range were inhibitory to strains of *Enterococcus*, *Streptococcus* (Group A), *Staphylococcus*, *B. subtilis*, *A. aerogenes*, and *E. coli*. From five to fifteen minutes after the oral or parenteral administration of gliotoxin to mice, guinea pigs and rabbits, the plasma of the animals inhibited growth of tubercle bacilli in dilutions as high as 1:320, and significant degrees of activity persisted for at least two hours thereafter in most instances. Urine procured from animals of all three species two to three hours after they have been given gliotoxin proved inhibitory to the growth of tubercle bacilli in dilutions from 1:320 to 1:1280. Despite prolonged administration of gliotoxin in doses calculated to provide inhibitory concentrations in the blood for a large part of each day, no favorable influence on the course of tuberculosis in mice was demonstrable.

Inactivation of influenza virus by oxidizing agents ROBERT R. WAGNER and IRVEN B. STACY, JR. (introduced by LAVERNE A. BARNES) *Naval Medical Research Inst., Bethesda, Md.* The PR8 strain of influenza A virus is inactivated *in vitro* by dilution in various oxidizing agents. Infectivity was determined by inoculation of chick embryos and the hemagglutinating capacity of harvested allantoic fluid. P-benzoquinone, potassium permanganate and sodium periodate were effective in inactivating up to 50,000 I.D. of virus. Oxygen, ammonium iodoxybenzoate and cytochrome C were ineffective and it appears that this inactivation is associated with dehydrogenation. Glucose counteracts the effect of periodate but not of quinone, permanganate or hydrogen peroxide. L-ascorbic acid, in equimolar concentration, is antagonistic to the action of all 4 compounds, L-cysteine protects only against quinone and peroxide. The degree of activity of these agents is roughly associated with the redox potentials, except for quinone which appears to exhibit greater specificity. These compounds, at 0.001 M concentration, destroy the capacity of the virus to be adsorbed onto chicken erythrocytes, this also correlates with loss of infectivity. However, virus treated with quinone at lower concentrations, although rendered non-infective, will retain its ability to be adsorbed. Furthermore, inactivation by low concentrations of quinone can be reversed by cysteine and glutathione but not by ascorbic acid. These preliminary results indicate that at 0.001 M concentrations these oxidizing agents act as denaturants of PR8.

March 1949

virus, but the site of action of quinone in lower concentrations may be on a sulfhydryl moiety of the virus and that this reaction involves no loss of adsorbability and is reversible

Antibody against encephalomyocarditis virus in the sera of American wild rats JOEL WARREN, SUDIE B. RUSS and HELEN JEFFRIES (introduced by JOSEPH E. SMADEL) *Dept of Virus and Rickettsial Diseases, Army Medical Dept Research and Graduate School Army Medical Center, Washington, D C* In the search for natural reservoirs of the viruses of the encephalomyocarditis group (Columbia-SK, M.M., E.M.C. and Mengo viruses) sera from various species of wild-caught rodents have been examined for the presence of neutralizing antibody for E.M.C. virus. Seventy-nine of 440 sera from *Rattus norvegicus* and *Rattus alexandrinus* possessed considerable amounts of neutralizing substances for E.M.C. virus. Tests performed intraperitoneally in mice showed that such sera were capable of neutralizing 1,000 to 100,000 MLD's of the agent. The geographic distribution of immune rats varied considerably. For example, of 40 rat sera collected in rural areas of the state of Mississippi 39 were positive, whereas only 9 of 75 from Florida and 9 of 64 from Georgia contained this antibody. In the state of California 11 of 32 rats from Orange county were positive while only 2 of 49 from San Diego county had antibody. In general, the incidence of rats with E.M.C. antibody was greatest in southern areas and least in northern regions. Indeed, none of the 38 sera from rats caught in the states of Michigan or Washington or in British Columbia possessed immune substances. None of the sera from a group of 61 rodents made up of jack rabbits, squirrels, marmots and chipmunks contained neutralizing antibody, even though they were trapped in regions where there were a number of E.M.C. immune rats. It appears that wild rats constitute one of the natural reservoirs of the E.M.C. group of viruses.

Role of cathepsin II in the mechanism of caseation in experimental tuberculosis of rabbits CHARLES WEISS and JULIUS SCHULTZ (by invitation) *Labys of the Jewish Hospital, Philadelphia, Penna.* One series of rabbits was infected intratracheally with 0.001 mg of a virulent (Ravenel) culture of *M. tuberculosis* and killed at intervals of from 5 to 20 weeks. A second series was sensitized with 2 successive weekly intravenous injections of 1 mg of a non-virulent R_1 strain, reinfected intratracheally 2 weeks later with a Ravenel culture, and treated similarly. Sections of lung and kidney showed histologically varying amounts of caseation, usually surrounded by granulomatous tissue. Weighed organs, preserved in a dry ice refrigerator, were homogenized in a Waring blender and cathepsin II estimated (Method of estimating hydrolysis of BAA was described by

Schultz, J., *Jour Biol Chem* 1948, in press). After primary infection with virulent tubercle bacilli, the catheptic activity of certain organs was altered. While there were individual variations, there were statistically significant decreases in the hydrolysis of BAA by the livers and kidneys of rabbits killed 5 weeks after primary infection. The lungs, now weighing 2 to 10 times their normal values, had 2 to 10 times the normal enzymatic activity based on total organ content. The animals which were first sensitized with R_1 cultures and then reinfected with a virulent strain, showed decreases in the liver and marked increases in the kidneys and lungs, if killed 4 to 5 months after reinfection. Thus, the cathepsin II activity expressed as the first order reaction constants or $K/gm N$, were for normal liver, kidney, and lung 28 ± 2.1 , 24 ± 1.9 , and 8.6 ± 0.8 while those for the immunized and reinfected animals were 17 ± 2.1 , 38 ± 6.0 , and 2.1 ± 2.9 , respectively. In explanation the following is suggested. The liver is an organ of high natural immunity to infection with tubercle bacilli, hence, the bacilli of reinfection do not multiply actively there and do not call forth an intense mononuclear infiltration. The kidneys and lungs, on the other hand, possess much less natural immunity, therefore permit a greater multiplication of tubercle bacilli and a much more rapid and intense mobilization of inflammatory cells which are probably the source of much of this added enzyme.

Color reactions with malignant sera EMIL WEISS *Tumor Clinic, Michael Reese Hospital, Chicago, Ill.* A number of aniline dyes in dilutions 1:10,000 do not show any color changes on addition of malignant sera. Sera of normal individuals, those afflicted with various diseases or benign tumors turn the original blue color of the same dyes green. The glassware must be clean and free of any acid or dye. The sera must be fresh and thoroughly centrifuged. Hemolyzed or icteric sera can not be used. The dyes are kept in 0.1% stock solutions of rubbing alcohol (70% isopropyl alcohol). The stock solution is diluted with distilled water 1:10 before use. To 0.5 cc of the diluted dye 0.5 cc of serum is added, the tube is shaken for a few seconds and the color changes are noted. A positive control containing a known malignant serum and a negative control containing a known normal serum are handled in the same manner. A dye control correspondingly diluted with water also is used. The tubes are placed overnight or for 12 hours in the refrigerator and then the final reading is made. Eventual color changes become more distinct after standing several hours. Over 300 sera were examined with the above technique. Positive (blue) reactions were obtained in 89.1% of malignant sera. Azur II, toluidine blue, trypan blue and victoria blue were found to be equally

useful This method applies to all types of malignancy Hodgkin's disease and various forms of leucemia give consistently positive results

Immunochemical studies on egg white proteins
L R WETTER, M COHN and H F DEUTSCH (introduced by A M PAPPENHEIMER, JR) *Dept of Physiological Chem, Univ of Wisc Medical School and Dept Microbiology, New York Univ, College of Medicine, New York City* Although chicken egg white (EW) possesses at least seven electrophoretic components, only ovalbumin has been extensively characterized Immunochemical methods were used to furnish information concerning the minor and poorly understood components of chicken EW The curve describing the quantitative precipitin reaction between EW and rabbit antisera is extremely complex Nevertheless, when purified preparations of ovalbumin, conalbumin, ovomucoid and lysozyme were used as precipitinogens, various portions of the curve could be ascribed to reactions between these proteins and their respective antibodies Although ovalbumin comprises 60% of EW, when the latter was used for immunization only a small proportion of the total antibody was directed against it Conalbumin induced greater antibody production than ovalbumin although it comprises only 16% of the total protein A very small proportion of the total antibody was directed against lysozyme and ovomucoid The major portion of the antibody was not directed against the above four components, which comprise approximately 95% of the total protein, but rather against the remaining 5% Rabbit anti EW sera were used to study the cross reactions of the antigens in chicken EW with the corresponding antigens in egg whites of turkey, guinea hen, goose and duck It was demonstrated that several other components cross react in addition to ovalbumin, especially those comprising the minor portion of chicken EW

Anaphylactic studies in mice A H WHEELER, E BRANDON, and H PETRENCO (introduced by REUBEN L KAHN) *Serology Lab, Univ Hospital, Ann Arbor, Mich* As is well known, mice do not respond typically to anaphylactic shock Experiments were carried out in this laboratory showing that, if mice are injected with egg albumin plus Freund's adjuvant and then challenged with the egg albumin, fatal anaphylactic shock occurs in about 60% of the animals Generally only about 10% fatality occurs in the control animals injected with the protein alone It was also observed that, following a challenge, abortion occurs more frequently in sensitized pregnant mice than in non-sensitized ones This finding suggests that in mice, abortion may prove a more sensitive indicator of anaphylaxis than anaphylactic death

Demonstration, occurrence and significance of iso-immunization against the A and B factors

during pregnancy ERNEST WITEBSKY *Dept of Bacteriology and Immunology, Medical School, Buffalo, N Y* Fifty cases of heterospecific pregnancies were examined for immune anti-A and immune anti-B isoantibodies Their presence was demonstrated by 2 methods One consisted in the replacement of saline solution by undiluted human serum and the second method by neutralization of the isoantibodies by means of the purified blood group specific substances followed by titration in saline solution as well as in undiluted human serum More than half of the cases examined did not reveal any trace of isoimmunization, others in varying degrees from slight to strong antibody formation Even in those few instances in which a potent immune antibody was found, the baby upon delivery proved to be normal In a series of investigations carried out independently from the 50 cases mentioned, 2 umbilical cord bloods were found whose cells proved to be sensitized when suspended in normal adult serum (9-drop method) The only clue which could be found for the cause of this phenomenon was isoimmunization against the A and B factor respectively It was interesting to note that in both instances the Coombs test was negative in our hands Only in one baby was there slight evidence of hemolysis and jaundice The only case of fatal erythroblastosis presumably caused by isoimmunization against the A factor so far experienced by us was that of a baby of blood group A born to a mother belonging to the blood group B (5th child) A potent immune anti-A antibody was found in the mother's circulation The baby's umbilical cord serum also contained an immune anti-A antibody whose strength roughly compared with the immune anti-A antibody present in the mother's serum following *in vitro* neutralization with A substance It is apparently much more difficult to neutralize immune anti-A antibodies than normal isoantibodies By comparing the cord serum with the mother's serum the impression was gained that the baby's body acted *in vivo* similar to the addition of A substance to the mother's serum in the test-tube The titer of both sera was somewhat alike The conclusion is therefore drawn that isoimmunization against the A and B factors is only a rare cause of erythroblastosis The demonstration of increasing antibody titer or even the presence of immune antibodies in the mother's serum is insufficient evidence to predict erythroblastotic changes in the newborn

Relationship of blood sugar and hypoproteinaemia to antibody response in diabetics MICHAEL G WOHL, S O WAIFE, STANLEY GREEN, and GEORGE B CLOUGH (introduced by MAX B LURIE) *Philadelphia General Hospital, Philadelphia, Penna* Diabetic patients have a lessened capacity to form antibodies The low antibody response to antigenic stimulation appears to bear
